Another important precursor of present-day bioprocessing is the fractionation of human plasma proteins for the production of its components: mainly, serum albumin, immunoglobulins, fibrinogen, and various clotting factors. Use of purified proteins is a far more efficient utilization of human plasma – an expensive national resource – than total plasma transfusion. The industry originated during World War II and is based on fractional precipitation of plasma component proteins by the addition of ethanol under controlled conditions of temperature, pH, and ionic strength. The ethanol process developed by Cohn and his numerous associates is used worldwide with remarkably few changes since its introduction.

Modern purification of therapeutic proteins that are produced through recombinant DNA technology is not based on ethanol precipitation; rather, it relies mainly on chromatography. Nevertheless, protein purification benefited enormously from the older plasma fractionation industry, which developed such essential ancillary equipment and processes as centrifuges, filters, freeze-dryers, sterile operation, pyrogen testing, and quality control. Plasma fractionation still handles much larger volumes of proteins and at a lower cost than any other form of therapeutic protein processing.

The use of radioisotopes and electron microscopes, also around World War II, contributed significantly to advances in bioprocessing. The use of these techniques to track isotopes in the body and to visualize cell components when combined with silicon transistors in the 1950s lead to the advanced diagnostic and analytical tools of today including nuclear magnetic resonance machines, gas and liquid chromatographs, ultrasound, laser and magnetic imaging techniques, and X-ray diffraction tools. These advances in instrumentation allowed for a switch from ''trial-and-error'' medicine and products to physiology-based biotechnology.

The current bioprocessing industry relies on several complementary technologies. The backbone of the industry is the use of recombinant proteins, obtained by inducing a host organism to express foreign proteins. To this end, a gene regulating the production of this protein is inserted into a plasmid, an autonomous, self-replicating piece of DNA that is inserted into a living cell. The host organism can be a bacterium, yeast, plant, mammalian, or insect cell, as well as an intact plant or higher animal. The first recombinant plasmid was patented by Cohen and Boyer in 1973. The plasmid is constructed to cause a cell to manufacture a large quantity of foreign or product protein (up to 50 g of protein per liter of cell medium). The excess protein is, in many cases, expressed in a denatured form as a densely aggregated particle. This step facilitates the purification of the protein, but it then requires solubilization and refolding in the biologically active form – an often daunting problem. Obtaining the active protein usually dictates the choice of plasmid and host cell.

The formulation of the original gene (i.e. the sequence of the nucleotides forming the DNA) is greatly facilitated by the polymerase chain reaction (PCR) method, first developed in the mid-1980s by the Cetus Corporation and commercialized by Perkin-Elmer. PCR is an enzymatic

process that is carried out in discrete cycles of amplification, each cycle doubling the amount of available DNA. Thus, minute quantities of a rare target sequence can be amplified to produce adequate quantities with excellent faithfulness. PCR is used to amplify DNA for protein products as well as for detection of trace quantities of contaminants. Specific sequences of DNA can also be chemically synthesized using solid-phase procedures.

A second important technology is the production of monoclonal antibodies. Sensitized antibody-producing spleen cells are hybridized with stable cancer cell lines; the so-formed hybrid has the longevity of typical cancer cells in tissue culture and the specificity of the original splenocyte. The reproducible character of the monoclonal antibodies has permitted the development of new diagnostic procedures of exquisite specificity, new protein separation specificity, and new therapeutics such as Herceptin, an antibody used to block the overexpressed Her2 receptor in breast cancer patients. While recombinant proteins can be expressed in all types of host cells like bacteria and yeast, the production of hybridoma cells requires more stringent and far more expensive mammalian tissue culture procedures.

A third major branch of biotechnology is the direct chemical synthesis of peptides using the solid phase methodology first developed by Bruce Merrifield, a Nobel laureate. The first amino acid of a desired peptide sequence is coupled to a latex particle, and subsequent amino acids are coupled to it, step by step, in highly automated instruments. The direct synthesis yields an easier approach for the synthesis of families of peptides differing in only a single amino acid, a point mutation. If the future holds more personalized pharmaceuticals through the field of pharmacogenomics (study of polymorphisms in drug-metabolizing enzymes and the resulting differences in drug effects), then the direct synthesis method may be the production method of choice.

A fourth major branch of biotechnology is genomics. Now that the human genome is sequenced, a huge amount of controversy surrounds the use of the information. Genes for diseases are rapidly being discovered, and medicines and therapies are based on knowledge that is more complete compared to the trial and error methods of the past. The genome sequence in combination with new techniques in combinatorial chemistry, a greater understanding of receptors, and improved data management tools using the fastest computers is opening up an entirely new type of bioprocessing industry. However, there is a huge amount of resistance from a variety of religious organizations fearing the loss of human individuality, and many other government agencies and individuals worldwide that are scared of transgenic plants and animals after a couple of incidents. Laws were passed or are under consideration in many countries to limit the use of genetics to protect human tissue use and track genetically modified plants from farm to consumer.

Detailed descriptions of all these and other current processes are beyond the scope of this brief review. Other articles within this encyclopedia discuss some in detail. Therefore, the key features of only five aspects of bioprocessing are presented: enzyme engineering, whole-cell reactors, transgenic plants and animals, transport and adhesion of cells, and bioseparations or downstream processing.

2 Enzyme Engineering

Enzymes are an alternative to viable cells for synthesis of biological products. The applications vary from alternative fuel synthesis to environmental remediation to biosensors to food processing to textiles. Enzymes themselves are also bioprocessing products. With the increased knowledge of recombinant DNA technology, rare enzymes are now made easily in large quantities and are obtained from organisms grown in unusual environments like hot springs or the ocean. One increasing area of enzyme use is in the separation of chirally pure compounds. Typically, one enantiomer in a mixture is often not useful while the other has therapeutic value. This unique enzyme function leads to the development of processes that use both chemical and enzymatic synthesis for the production of new pharmaceuticals.

The most common reactor configuration for enzyme synthesis of a product is a packed or fluidized immobilized enzyme reactor. This system has the advantage of being a continuous process able to handle high throughputs of process streams. Enzymes are reasonably protected in this environment. Cellulase is an example of an enzyme that is used in an immobilized configuration for the conversion of biomass feedstock in ethanol production for alternative fuels. In addition, these systems show promise for environmental remediation to selectively remove heavy metals or transform hazardous organic substances into nontoxic compounds.

Enzyme kinetics for simple enzyme-catalyzed reactions are often referred to as saturation or Michaelis–Menten kinetics. The reaction mechanism describing this process is

$$\mathrm{E} + \mathrm{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{ES} \xrightarrow{k_2} \mathrm{E} + \mathrm{P}$$

where E is the enzyme, S is the substrate, P is the product, ES is the enzyme–substrate complex, and the k values are the reaction rate constants. The scheme involves a reversible step for formation and dissociation of the enzyme–substrate complex. It assumes that the second reaction, product generation, is irreversible, which is a good assumption when product accumulation is negligible at the beginning of the reaction. To develop the rate expression for enzyme-catalyzed reaction, either a rapid equilibrium approach or a quasi-steady state approach is used. Either way, the resulting rate expression is

$$v = \frac{\mathrm{d}P}{\mathrm{d}t} = \frac{V_m \mathrm{S}}{K_m + \mathrm{S}} \tag{1}$$

where v is the reaction rate, t is time, V_m is the maximum forward reaction rate, and K_m is the Michaelis–Menten constant. This rate expression is commonly used to describe enzyme-catalyzed reactions. Many enzymatic reactions are described by Michaelis–Menten kinetics. The rate constants are usually determined from initial rate experiments.

Enzymes are effected by pH and temperature. Typically, an enzyme is active only over a certain pH (1 to 2 pH units) and temperature range (5 to 10°). The pH and temperature effects are incorporated into the enzyme kinetic expression when needed. Enzymes are also inhibited by many heavy metals or organic materials. The inhibitors bind to the active site of the enzyme directly (competitive inhibition), to another site on the enzyme, thus reducing the enzyme affinity for the substrate (noncompetitive inhibition), or to

the enzyme–substrate complex (uncompetitive inhibition). All these cases result in reduction of the enzyme-catalyzed reaction rate. In addition, the substrate itself or the product formed may be inhibitory, also resulting in a decrease in reaction rate.

When immobilized reactors are utilized, the reaction may be diffusion limited. A concentration gradient causes the substrate molecule to move, and this movement may be slower than the enzyme-catalyzed reaction rate. The diffusion rate is a function of temperature, pressure, and the composition of the system. If a porous support is used, the following equation is used to describe the enzyme kinetics:

$$D_e\left(\frac{d^2S}{dr^2}+\frac{2\,dS}{r\,dr}\right)=\frac{V_mS}{K_m+S} \qquad (2)$$

where D_e is the effective diffusivity of the substrate within the porous support matrix, and r is the radius of the porous support. This expression assumes the following:

- The system is at steady state.
- Flux is by diffusion only, not convection.
- Diffusion is governed by Fick's law.
- The enzyme-catalyzed reaction follows Michaelis–Menten kinetics.
- The substrate does not adsorb to the support.
- The support matrix has a constant void volume.
- The enzyme is evenly distributed within the support matrix.

Enzyme technology is exploited in the area of biosensors. Enzyme-coated electrodes provide a highly selective and sensitive method for determining the amount of a given substrate. Examples of electrodes include sensors for fermentation products and intermediates (e.g. amino acids, lactic acid, penicillin, alcohols). Current research involves coupling enzyme reactions to improve sensitivity by eliminating interfering signals, as well as improving enzyme stability by using enzymes isolated from organisms that live in extreme environments like hot springs or oceans. The use of these specific electrodes facilitates the control of bioprocesses, resulting in higher productivity. Biosensors are also playing an increased role in medical applications like the detection of glucose in blood and urine and detection of scarce enzymes such as tissue plasminogen activator. Future use will also involve detection of biological and chemical contaminants in the environment and in water supplies as security tightens around the world.

For everyday use, the food and detergent industries purchase the largest amounts of enzymes. Proteases that hybridize proteins into smaller peptide units constitute the largest part of the enzyme market. They are used in cheese making, baking, meat tenderizing, brewing, tanning, and detergents for the hydrolysis of protein stains. Other enzyme uses include medicine (penicillinase removes penicillin from an allergic individual and trypsin is used as an anti-inflammatory agent); pulp and paper manufacture (lignases biopulp wood); and the textile and leather industries. The issue becomes one of how to process or cheaply make large quantities of the enzymes. This leads to the next area of the bioprocessing industry – live cell bioreactors.

3 Whole-cell Bioreactors

Living cells can be viewed as small biochemical reactors of great complexity. They are utilized in most aspects of biotechnology, and most biotechnology

processes begin with a bioreactor. Despite the advances in enzyme technology, it is important to keep in mind that enzymes come from cells; thus, whole-cell bioreactor technology will be important for enzyme production as well as for production of vaccines, insecticides, antibodies, hormones, immunobiological regulators, and artificial tissue.

The roots of fermentation technology are traced back to many centuries. The earliest bioreactors or fermentors were used in the brewing and wine-making industries. During the last 50 years, fungal fermentations have been used to make antibiotics, beginning with penicillin. Recombinant DNA technology, monoclonal antibody production, and genomic research continue to push the whole-cell reactor technology forward. The first major products made by recombinant organisms were insulin (Eli Lilly), tissue plasminogen activator (Genetech), and erythropoietin (Amgen). Today the major question that remains is how to choose the best host–vector system. The most common hosts for commercial production are the bacterial strain, *Escherichia coli*, and the Chinese hamster ovary (CHO) cells. A comparison of the advantages and disadvantages of using these two types of cell systems is given in Table 1. Overall, the choice of the host–vector system is very complicated and the ''ideal'' system does not as yet exist. The characteristics of the protein product and cost are the critical values. For example, if a bulk enzyme for detergents is being produced, some impurities are okay, and bacterial

Tab. 1 Comparison of bacterial and mammalian cell host–vector systems for product synthesis.

E. coli cultures		*CHO cell cultures*	
Advantages	***Disadvantages***	***Advantages***	***Disadvantages***
High growth rate	Formation of inclusion bodies	Availability of host and vector systems	Slow growth
Wide range of host backgrounds	Misfolded protein products	Excretion of product	Expensive, complex media
Wide range of vectors and promoters	No ability to glycosylate	Ability to produce authentic proteins (correct folding, glycosylation, and posttranslational processing)	Low protein expression levels
High expression levels and cell densities	Proteolytic activity	Low proteolytic activity	Shear sensitive cells
Low-cost media	Usually low levels of product excretion		Vectors are derived from virus and there is fear of reversion to pathogenic form.
	No posttranslational processing		Must assure removal of nucleic acids from hybridoma lines
	Must assure removal of endotoxins during purification		Most strains are mortal so dead cells must be removed.

or yeast cultures are more often used. Large protein molecules and antibodies are made only in mammalian cultures and product purity is paramount if the product is an injected biopharmaceutical. Compounds such as insulin or tissue plasminogen activator are made in either system – bacterial or mammalian.

In addition to *E. coli* and CHO cells, other types of bacterial cells, yeast, plant cells, and insect cells have been studied for synthesis of bioproducts. Gram-positive bacteria such as *Bacillus subtilis* excrete proteins better but make more proteases that rapidly degrade the protein products. The yeast strain, *Saccharomyces cerevisiae*, is used in the food industry and the genetics are reasonably well understood; however, it tends to express only low levels of a foreign protein and hyperglycosylates the product. Plants themselves offer the advantage of diversity. As much as 25% of today's pharmaceuticals (primarily nonprotein products) are extracted from plants. Plant cell cultures do allow for more control than using an intact plant; however, genetic knowledge is less than what is known for bacterial and animal cells, and product expression levels are low. Only a few plant cell systems are used commercially in Japan and Germany. The most well known product made in plant cell culture is the anticancer agent, paclitaxel or Taxol. The insect cell–baculovirus system is used primarily as a research tool and for small-scale studies (100 L). The advantages of this system are that it does allow for high expression of foreign protein and offers potential safety advantages, since virus that affect insect cells do not affect humans. However, the insect system does not quite mimic the mammalian cell system in that the protein product may have slight structural modifications, which are useful when making vaccines but not necessarily so for complex products.

Optimization of recombinant protein production is a continuing objective of industrial and academic research. Engineering and science work together to reach this objective. For instance, a common problem is genetic instability (segregational, structural, host cell gene mutation, and/or growth rate dominated), since the overproduction of foreign proteins is always detrimental to cell growth and survival. Novel reactor strategies developed to alleviate segregational instability include selective recycle reactors in which productive plasmid-bearing cells are selectively recycled to a fermentor through flocculation and size separation, while nonproductive rapidly growing cells and/or dead cells are removed from the reactor. Thus, a productive, continuous reactor can exist "in theory" for infinite time. Cells have been genetically manipulated to alleviate this problem as well, by inserting antibiotic resistance genes into the plasmids and supplying antibiotics to the medium. Research continues to find the "ideal" host–vector system, which rapidly grows and expresses high levels of foreign protein that are excreted. The ideal system also does not produce proteases, and folds and glycosylates the protein product as required.

The newest area of bioreactor research and development is the growth of tissues in biofilm or scaffold reactors for regeneration of tissues. Great strides continue to be made. For example, it is now possible for a patient's cells to be shipped to a company, cultured in a scaffold bioreactor and subsequently reimplanted. Regenerative and rejuvenating therapies may become common in the near future. Human genes, proteins, antibodies, and cells are used in combination to replace, repair, and restore

tissue that is damaged by disease, injures, or old age. Tissue cell reactors for these purposes require precise control compared to those used for the production of food or pharmaceutical products, but the principles of operation build upon the knowledge learned from existing whole-cell bioreactors. A more controversial area of research is the use of stem cells for medicinal purposes. The ethical issues surrounding this type of work may slow its development but these areas will be an important part of the next few decades of research.

Various models ranging from unstructured, nonsegregated to structured, segregated are used to describe cell growth. The most common kinetic expression is the Monod equation:

$$\mu = \frac{\mu_{\max} S}{K_s + S} \qquad (3)$$

where μ is the specific growth rate, $\mu_{\max}$ is the maximum specific growth rate, K_s is the saturation constant, and S is the substrate. This growth expression is inserted into batch, continuous, biofilm, scaffold, or immobilized reactor equations to predict the rate of utilization of substrate, cell concentration, and growth-associated product concentration. The semi-empirical expression assumes that a single chemical species, *S*, is limiting, while changes in other nutrient concentrations have no effect; and that a single enzyme system with Michaelis–Menten kinetics is responsible for the uptake of *S*. Although this premise is seldom true, the Monod equation is used routinely to describe bioreactor behavior of everything from well-defined recombinant bacterial or mammalian systems to wastewater treatment systems. Growth rates are affected by temperature, pH, and media composition.

Chemically structured models provide a more general approach with greater predictive power by relating cell growth and product production not to just one substrate, but to nitrogen, carbon, and oxygen uptake, as well as including expressions that relate important kinetic interactions among cellular subcomponents such as RNA, DNA, lipids, and proteins. These more sophisticated models predict growth rates better and, thus, reactor behavior, but consist of between 4 and 40 equations. Segregated models typically differentiate between productive and nonproductive cells within one reactor system. The very complex models are not typically used by industry but are used in some research laboratories.

4 Transgenic Animals and Plants

A technology that has made great strides in the past decade is the use of transgenic animals and plants for production of proteins. The living animal or plant becomes the ''bioreactor''. The use of transgenic animals is less developed than that of plants. Animals have the advantage of performing complex posttranslational processing steps that cannot be done in animal cell culture. How it works is that new genetic information is inserted into the embryo of the animal and the nontoxic protein is expressed by the mature animal – typically in the milk. High concentrations of complex proteins are achieved, and the processes can be made cost effective. Sheep, goats, and pigs are the primary species being evaluated for this task. Harvesting the milk and downstream processing technologies are areas of current study. In addition, there are some serious concerns about the use of

animals to produce proteins. The primary concern is safety. Besides the possibility of having a negative health effect on the animal, there is fear regarding mutation of animal viruses that jump species and become a serious health issue for humans. The fear is real since some viruses such as AIDS and SARS that still lack effective treatment are believed to have originated in animals. Screening of animals for viruses is an extremely expensive undertaking and may limit the cost effectiveness of their use for production.

Transgenic plant technology holds great promise and products are currently in Phase I clinical trials. Large companies including Monsanto, Dow Chemical, and Sigma-Aldrich are teaming with smaller companies such as Prodigen, Inc. and Epicyte Pharmaceutical to manufacture antibodies and proteins in transgenic plants. Several crops including corn, tobacco, potatoes, and soybeans have been studied for production of antibodies and proteins. Products tend to degrade within the tobacco leaf and potato; protein separation from soybeans is more challenging; but corn results are very promising. The product, especially antibodies, concentrates in the corn kernels, and is easily separated. The demand is for ''green'' engineering processes. The desire is to eliminate environmental hazardous waste generation altogether. Thus, a green plant that works as a bioreactor is an extremely attractive, environmentally friendly alternative. The systems are also safe in terms of virus transmission, since plant viruses do not survive in animals. One concern is the ability to keep the plants isolated from other crops. The pharm plant products, as they are being called, cannot be allowed into the food chain. So currently these plants are not grown in any food producing areas. The tremendous advantage of using pharm plants to make antibodies and other products is that the estimated production costs are an order of magnitude less than the cost of production using mammalian cells. This savings will push the development of transgenic plant products forward.

5
Transport and Adhesion of Cells

Cellular and viral transport and adhesion are important in immobilized reactors, the development of new drugs, tissue repair, drug delivery, *in situ* bioremediation efforts, and security issues related to bioterrorism. Understanding how cells are able to recognize and adhere specifically to insoluble extracellular tissue matrix proteins and to other cells is crucial to many physiological processes. Cells of all types – blood, bacterial, tumor, and endothelial – respond to environmental stimuli through receptors found on their cells surfaces. For example, a cell will have a receptor on its surface for epidermal growth factor; binding and internalization of the growth factor then stimulates DNA synthesis. Cell receptors are responsible for cell adhesion to surfaces such as tissue, scaffold reactors, and for self-agglutination. White blood cells adhere to ligands on vessel walls, or mammalian cells adhere to surfaces coated with ligands through integrins. Cell receptors are also responsible for chemotaxis – the migration of cells in response to a specific chemical gradient. Chemotaxis is of particular importance in the development and repair of inflammations.

Understanding the mechanisms of intra- and intercellular transport is the key to the development of site-directed or target-specific drugs. For instance,

monoclonal antibodies may be used to deliver drugs to cancer cells only through specific ligand–receptor binding. Gene therapy relies on a better understanding of developing vectors to deliver genes and proteins to specific targets, to deliver vaccines, for example. Animal models are improving and the future may hold more gene therapy for humans, although this is another area of controversial research and application.

Understanding cellular transport also aids in environmental remediation. Once microorganisms have been injected into the environment, they must move from the point of injection to the contamination site. Cell receptors known as *pili* or *fimbriae* are responsible for some cell adhesion to the soil, minerals, and other contaminants in soil. Polysaccharide production is also responsible for cell adhesion. If pilin and polysaccharide synthesis and binding mechanisms are understood, the efficiency of using biodegradation to remediate soil and water can be determined through process engineering analysis and compared to other existing technologies such as chemical oxidation and incineration.

A growing area of concern is the understanding of pathogen transport through water systems. Once a bacterial or viral pathogen enters a water supply, it is important to understand how its transport can be limited. Efficient, cost-effective alternatives for pathogen death and removal are currently being investigated, as well as the fundamental principles influencing pathogen transport such as the effect of minerals, organics, and temperature. Since the environment in which we live is complex and changing, how a pathogen behaves in a particular environment is still not well understood.

6 Bioseparations

Although a large quantity of work has been done on fermentation and other upstream processing, the main cost of making a biotechnological product is in the downstream processing or separation steps. Improved methods are always needed, since most of the separation equipment employed are simple scale-ups of analytical and micro-preparative techniques pioneered in life sciences laboratories.

After a product is made by a cell or a plant, it needs to be separated from the rest of the by-products. The standard industrial separation techniques for separating cells from spent media entail either centrifugation or cross-flow filtration. If the cell product is an intracellular product, the cells must be lysed through homogenization, osmotic shock, or bead milling. Then the cell debris is removed by centrifugation or filtration. Bacterial products tend not to secrete protein products and require this step, whereas mammalian cells typically do secrete. The expensive part is further purification of the product. For soluble protein products, all of the cellular protein is usually precipitated as a first step by changing the temperature or ionic strength or by adding a solvent such as ethanol. The purity and efficiency of the process is governed by thermodynamics – in particular, by the chemical potential of the precipitant and the solution. A number of technologies exist for further product separations, depending on the purity of the product required. These include affinity, ion exchange, reversed phase, size exclusion and other forms of chromatography; electrophoresis; liquid–liquid extraction; membranes; and distillation. There are process design heuristics for purification/separation,

which include steps such as separating the most plentiful impurities first; performing the most difficult and costly separations last; and sequencing processes to exploit different separation driving forces such as size, charge, and differences in boiling points.

Chromatography is defined as the separation of substances by the selective binding of components to porous, solid, sorptive media. Various types of chromatographic separation are employed including adsorption, liquid–liquid partition, ion exchange, gel filtration or molecular sieving, affinity, hydrophobic and high performance liquid chromatography or HPLC. Typically, a combination of chromatographic processes is used to purify proteins. For example, an ion exchange column separates negatively charged products from positively charged and neutral products, whereupon the desired products are isolated by means of an affinity column. Affinity chromatography is particularly versatile, often displaying exquisite selectivity. Various affinity systems are used such as antigen–antibody, lectin–carbohydrate moiety, enzyme–substrate, immobilized metal ion-histidine-containing protein, receptor–hormone, and so on. In addition, affinity chromatography may be used for environmental remediation using ligands (chelators or macromolecules) that specifically bind metal ions.

Since chromatography involves the adsorption of species to be purified (i.e. a protein) to a support for separation, the process is often described by either Freundlich or Langmuir isotherms. An empirical formula that describes the adsorption of many antibiotics, hormones, and steroids is the Freundlich isotherm:

$$q = Ky^n \tag{4}$$

where q is the amount of solute (product or contaminant) adsorbed per amount of adsorbent, y is the solute concentration in solution, K is similar to an equilibrium constant, and n is an empirical constant. The values of K and n are determined experimentally. If the adsorption is favorable, then $n < 1$; if it is unfavorable, $n > 1$. The Langmuir isotherm is not empirical; instead it has a theoretical basis:

$$q = \frac{q_0 y}{K + y} \tag{5}$$

The values of q_0 and K are determined experimentally. This equation assumes that there are a specific number of active sites; the amount of sites for a given adsorbent is reflected in the value of q_0. At low solute concentrations, $q = q_0$. The Langmuir equation also assumes that an equilibrium is reached between adsorption and desorption to the active sites. Other assumptions are that adsorption takes place monomolecularly and is localized. The only disadvantage of chromatographic processes is that large columns are sometimes required that result in large pressure drops over the columns, requiring large auxiliary equipment like pumps.

Electrophoresis is used for the separation of charged molecules based on differences in both size and charge in an electric field. The separation is accomplished by balancing the drag force of a charged particle with the electrostatic forces when the particle is moving with a constant velocity. The net charge, q, on a protein determines its velocity, V_t, and thus its separation:

$$V_t = \frac{qE}{3\pi\mu D_{\mathrm{P}}} \tag{6}$$

where E is the electric field intensity, D_P is the particle diameter, and μ is the viscosity. The pH of the solution greatly affects the

separation. The major drawback of traditional electrophoresis is lack of scalability. Thus, electrophoresis has not made significant inroads into protein downstream processing, although two research-scale instruments are commercially available. Both are based on isoelectric focusing in free solution and do not need gels or other supporting matrices. Preparative isoelectric focusing does not require expensive buffers and is more easily scaled up.

Liquid–liquid extraction originally used immiscible liquids such as an organic and an aqueous phase. For example, an aqueous DNA solution is extracted with phenol and ether to remove lipids and other cell debris. Extraction is used to separate inhibitory end products such as alcohols from fermentation broths, or to recover antibiotics. However, organic solvents are not compatible with many proteins. Instead, protein separation is accomplished by means of aqueous two-phase extraction. Typical aqueous phases contain water-soluble but mutually incompatible polymers such as polyethylene glycol and dextran. The latter polymer, or any other bottom phase polymer, such as cellulose derivatives, may be substituted by highly concentrated salt solutions.

Partitioning of the solute or protein is described using a partition coefficient, K:

$$K = \frac{x}{y} \tag{7}$$

where x is the concentration of protein in the lighter liquid phase and y is the concentration of the same protein in the heavier liquid phase. The value of K is governed by thermodynamics; the logarithm of K is proportional to the difference in the chemical potentials of the standard states of heavy and light liquids. Factors that affect the partition coefficient include temperature, ionic strength, and pH.

Membranes are used to concentrate products and to clarify solutions; they are used to separate proteins based on size. Membranes are used to purify water through reverse osmosis. Filtration is generally governed by Darcy's law, which relates the velocity of the liquid through porous media, v, to the pressure drop ΔP:

$$v = \frac{k\Delta P}{\mu l} \tag{8}$$

where k is the permeability constant, which is a function of the filtrate, μ is the viscosity of the liquid, and l is the bed or membrane thickness. Darcy's law holds for low Reynolds number flow. The major drawback of membranes is biofouling. Layers of proteins build up on the surface and clog the membranes. Cross-flow or tangential-flow filtration decreases fouling, but does not eliminate it.

Other separation processes include crystallization – typically the last step in producing highly purified products like antibiotics, and drying to remove any solvents. The focus for the future continues to be combining techniques such as chromatography with membranes or chelators with liquid–liquid extraction. Furthermore, clever methods to combine fermentation and separation are always being investigated, since optimization of both will lead to the most cost-effective process.

Finally, an essential part of all downstream processing is quality control – the assessment of sterility, absence of genetic materials such as viruses or nucleic acids, and absence of pyrogens, as well as the purity of the final product such as the desired protein or antibody. Various chromatographic, mass spectrometric, and electrophoretic processes are routinely used for quality assurance. These techniques, when combined with

immunochemical reagents, allow for product and contaminant identification. The advent of multidimensional nuclear magnetic resonance, DNA hybridization, and Fourier-transform ion cyclotron resonance in tandem with large advances in computer technology significantly impact the ability to perform bioanalytical analysis. These techniques, while typically used more during the research and development stage, open the door for better methodology for product purity and safety.

7 Concluding Remarks

Currently, biopharmaceuticals constitutes only about 8% of the worldwide drug market, and is expected to grow to reach about 15% of the drug market by 2006. However, biopharmaceuticals is only one part of the bioprocessing market. Bioprocessing involves the collaboration of scientists and engineers from industry, government agencies, and universities. Systems biology is the wave of the future to evaluate all multivariable components simultaneously. Thrusts for expansion include developing combined reactor–separator equipment, pharm plant systems, human therapeutics, better and more vaccines and antibiotics, commodity chemicals, bioremediation, proteomics, instrumentation and software, ''biochips'', and gene and rejuvenative therapies. Legislation addressing the use of stem cells, gene therapy, transgenic animals, environmental remediation and emissions, and genetically engineered foods will have a tremendous impact on the future of the bioprocessing industry. Advances in current bioprocess techniques will be of essence if the cost of production is to be reduced. The competition is international and there are currently many company mergers. All are trying to be at the forefront of bioprocessing technology.

Keywords

Electrophilic
A compound, group, or function that is electron deficient and therefore preferentially reacts with electron-rich moieties.

Endobiotic
A compound that is endogenous to the organism.

LogP
The log of the partition coefficient for a compound between an organic solvent, often octanol, and water.

Nucleophilic
A compound, group, or function that is electron rich and therefore preferentially reacts with electron-deficient moieties.

Prodrug
A structure without a desired pharmacological property that is converted by metabolism to a product that has the desired property.

Xenobiotic
A compound foreign to the organism.

Drug and xenobiotic metabolism converts the lipophilic compounds that can be absorbed into the body into polar, excretable products, thus preventing their accumulation, but also sometimes forms more toxic products.

1 General Purpose of Xenobiotic and Drug Metabolism

Life is based on the organization of biological systems into compartments segregated by means of lipid bilayer membranes. This applies to subcellular organelles such as the nucleus and mitochondria, to the cells themselves, and through the assembly of cells into surfaces, to organs, and larger entities. The membrane barriers prevent the passage of charged or highly polar molecules, with the exception of small molecules that diffuse through pores in the membrane barriers, molecules for which active transport systems exist, or molecules taken up during pinocytosis. Lipophilic molecules can cross the membrane barriers relatively unimpeded unless they are so lipophilic that they are effectively trapped within the membrane. In contrast, mammals and other complex organisms only efficiently excrete polar or ionic compounds because lipophilic compounds are readily reabsorbed from excretory compartments such as the kidney. Thus, the properties that allow a xenobiotic to be taken up by a biological system are the

very same properties that militate against its excretion.

The primary purpose of xenobiotic metabolism is to convert lipophilic compounds to polar materials that can be eliminated. For this reason, the highest concentrations of enzymes of drug metabolism are found at sites that are portals of entry into the organism, such as the lungs, intestine, and liver of mammals. It is instructive in this context to consider the example of compounds, typified by manmade polyhalogenated aromatic hydrocarbons, that are poorly metabolized by the enzymes evolved for the metabolism of natural products. Compounds such as the highly halogenated biphenyls accumulate in adipose tissues and a major fraction remains there for essentially the lifetime of the individual. This accumulation of lipophilic, poorly metabolized compounds in fatty tissues is the basis for the well-known concentration of xenobiotics in natural food chains.

2 Classification and Properties of Enzymes of Xenobiotic Metabolism

The enzymes of drug metabolism predominantly catalyze oxidation/reduction, hydrolysis, and conjugation reactions, although there is some ambiguity in assigning enzymes to the drug-metabolizing system. For organizational purposes, the redox and hydrolytic enzymes are considered to be responsible for early stages of xenobiotic metabolism and are known as Phase I enzymes. The conjugative enzymes are usually responsible for the later transformations in a metabolic sequence and are known as Phase II enzymes. This classification is artificial because Phase II conjugation reactions need not be preceded by Phase I reactions, although it is true that Phase I redox or hydrolytic reactions usually occur before the Phase II conjugations that make compounds highly polar. Phase I xenobiotic metabolism is largely catalyzed by cytochrome P450 and flavoprotein monooxygenases, monoamine oxidases, alcohol and aldehyde dehydrogenases, esterases and amidases, and epoxide hydrolases. The enzymes involved in Phase II metabolism are primarily the glucuronyl transferases, sulfotransferases, *N*-acyl transferases, methylases, and glutathione transferases. Despite their involvement in drug metabolism, some members of both the Phase I and Phase II classes of enzymes are primarily or exclusively involved in the processing of endogenous substrates. Furthermore, many drugs resemble endogenous substances and are subject to metabolism by the more specialized enzymes involved in processing of endobiotics. For example, fatty acid β-oxidation, a pathway for the catabolism of endogenous fatty acids, also degrades xenobiotic alkyl chains that terminate in carboxyl groups.

Some generalizations can be made concerning the properties of enzymes that are primarily devoted to xenobiotic metabolism. In contrast to enzymes that process endobiotics, the enzymes of drug metabolism have broad substrate specificities and are stereoselective rather than stereospecific. There are not many classes of drug-metabolizing enzymes, but each class encompasses multiple enzyme forms. This combination of loose substrate specificity and enzyme multiplicity provides the flexibility required to metabolize the diversity of natural and manmade substances to which organisms are routinely exposed. The ability to deal with specific xenobiotics is enhanced by the

fact that the concentrations of some of the enzymes, most notably the cytochrome P450 monooxygenases (see Sect. 3.1), are transiently increased by exposure to specific substrates or inhibitors. This selective induction of enzyme forms that are required to deal with specific xenobiotics enhances the flexibility of the system in its response to xenobiotic exposure.

3
Phase I Enzymes

3.1
Cytochrome P450 and Flavin Monooxygenases

The mammalian cytochrome P450 monooxygenases are membrane-bound hemoproteins that are found in highest concentrations in the liver, kidney, nasal tissues, and lungs but are present in smaller amounts in most other organs. The name cytochrome P450 derives from the distinctive absorption maximum at approximately 450 nm of the ferrous–carbon monoxide complex of these enzymes. The genes for more than 1000 cytochrome P450 enzymes have been identified in prokaryotic and eukaryotic species. Approximately 60 such enzymes are found in the human genome. A nomenclature system has been developed that is based on division of the superfamily of cytochrome P450 enzymes according to their degree of sequence identity. With few exceptions, the members of a cytochrome P450 family share >40% amino acid identity and the members of a subfamily >55% identity. In this nomenclature, cytochrome P450 enzymes are designated as, for example, CYP4A1, in which the number after the prefix CYP identifies the family, the subsequent letter the subfamily, and the final number the individual enzyme within the subfamily. A similar nomenclature has been developed for other families of drug-metabolizing enzymes, including the glucuronyl transferases and sulfotransferases. Citations prior to 1987 employ nonsystematic nomenclatures.

The tissue levels of the different cytochrome P450 enzymes in an individual are controlled by genetic and environmental factors. Genetic variability in the expression of the various cytochrome P450 enzymes is well established and gives rise to populations with distinct metabolic patterns. Important differences exist in the ability of individuals to metabolize drugs owing to the existence of populations with high and low activities of, for example, the CYP2D6 form of cytochrome P450 responsible for the metabolism of debrisoquine and a variety of other drugs. In addition to genetic factors, the levels of cytochrome P450 enzymes are modulated by diet, age, disease, gender, and hormonal status. The ability of drugs and xenobiotics to alter the profile of cytochrome P450 enzymes in an individual by elevating the concentrations of specific forms is particularly relevant in this context. The increase in the levels of certain enzymes by a xenobiotic, termed *enzyme induction*, can be mediated by several mechanisms, among which the most important are an increase in transcription of the message for the enzyme, stabilization of the RNA transcript, and stabilization of the enzyme itself.

The mechanism of induction of the cytochrome P450 enzyme CYP1A1 involves binding of the inducer to a soluble receptor, termed the *aryl hydrocarbon receptor* (or AHR), that translocates to the nucleus and enhances the expression of the appropriate gene. Comparable receptor-mediated mechanisms have more recently been identified for the induction of other classes of cytochrome P450 enzymes. The classical

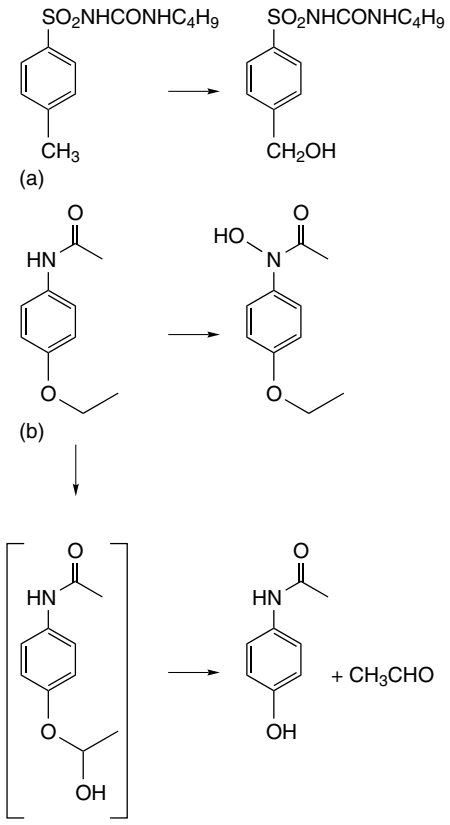

Fig. 1 Examples of cytochrome P450–catalyzed hydroxylation reactions. Hydroxylation of the methyl group in tolbutamide (a) and the amide nitrogen in phenacetin (b) yields, respectively, the corresponding alcohol and *N*-hydroxyamide metabolites. Alternative hydroxylation of the ethyl ether function in phenacetin produces a hemiacetal that decomposes to the phenol and acetaldehyde, a classic example of a cytochrome P450–catalyzed *O*-dealkylation.

cytochrome P450–inducing agents are phenobarbital, the polycyclic aromatic hydrocarbons, clofibrate, and agents such as dexamethasone, although compounds as simple as ethanol are known to elevate the concentrations of specific cytochrome P450 enzymes. In a general sense, the cytochrome P450 enzymes that are induced are those that bind, and usually metabolize, the inducing drug or xenobiotic. The induction response thus permits the organism to increase its ability to clear offending xenobiotics.

Cytochrome P450 monooxygenases catalyze the insertion of one atom of molecular oxygen into their substrates with concomitant reduction of the other oxygen atom to a molecule of water. The electrons required for this reductive activation of molecular oxygen are provided by reduced pyridine nucleotides. A flavoprotein known as cytochrome P450 reductase mediates the transfer of electrons from NADPH to the cytochrome P450 enzymes of interest in mammalian drug metabolism. The mitochondrial cytochrome P450 enzymes are primarily involved in the metabolism of endogenous sterols and, like most bacterial cytochrome P450 enzymes, obtain their electrons from NADH via a two-protein system consisting of a flavoprotein reductase and an iron sulfur protein. In contrast to the diversity of cytochrome P450 enzymes, there is relatively little diversity in the reductase components.

One of the three general oxidative reactions supported by cytochrome P450 is insertion of the catalytically activated oxygen atom into a C–H or N–H bond to give the corresponding hydroxylated product (Fig. 1). In principle, the oxygen can be inserted into the bond between a hydrogen and any other heavy atom. In the absence of enzyme-imposed steric or substrate orientation factors, the reactivity of a C–H bond is inversely correlated with the strength of the bond, so that tertiary alcohols are more easily formed than primary alcohols. One consequence of this is that

hydrocarbon chains are most commonly hydroxylated at the next-to-the-last ($\omega - 1$) position, although the CYP4 family of cytochrome P450 enzymes has specifically evolved to promote the thermodynamically more difficult terminal (ω) hydroxylation of fatty acids. Oxidation by cytochrome P450 is particularly critical for hydrocarbons and other nonpolar structures that do not have a functional group that can be used for further metabolism. This is clearly illustrated, as already mentioned, by the fact that polyhalogenated hydrocarbons (e.g. hexachlorinated biphenyls) that are resistant to cytochrome P450–catalyzed oxidation are very poorly excreted and accumulate in adipose tissue.

The diversity of the products formed by the cytochrome P450 system is greatly enhanced by the decomposition or rearrangement of unstable oxidation products to stable metabolites. The best example of this is hydroxylation adjacent to a heteroatom, which is normally followed by elimination of the heteroatom and conversion of the hydroxyl group to a carbonyl function. Alkyl ethers are thus *O*-dealkylated (Fig. 1), alkyl amines *N*-dealkylated, alkyl thioethers *S*-dealkylated, and alkyl halides dehalogenated.

The second general cytochrome P450 reaction is transfer of the activated oxygen to the π-bond of an olefin, an aromatic ring, or another unsaturated substructure to give the epoxide or a product formally obtained by rearrangement of such an epoxide. In general, electron-rich π-bonds are more readily oxidized than electron-deficient π-bonds. The epoxides formed in this reaction are relatively reactive and potentially toxic, but their toxicity is attenuated by the presence of epoxide hydrolases (see Sect. 3.6) and glutathione transferases (see Sect. 4.5) that convert the epoxides to less-reactive vicinal diols and glutathione adducts, respectively. The oxidation of aromatic rings yields particularly unstable epoxides that are subject to the so-called *NIH rearrangement* to give phenolic products (Fig. 2). Indeed, it is unclear in some instances whether the epoxide is an actual intermediate or a species closer to a transition state in the conversion of the aromatic ring to a phenol.

The third general cytochrome P450 reaction is addition of the activated oxygen to the electron pair of a heteroatom. A trisubstituted nitrogen is thus converted to an N-oxide and a disubstituted sulfur to a sulfoxide (Fig. 3). Whereas hydroxylation and epoxidation reactions are primarily catalyzed by cytochrome P450, the oxidation of heteroatoms is also catalyzed by flavin-containing monooxygenases.

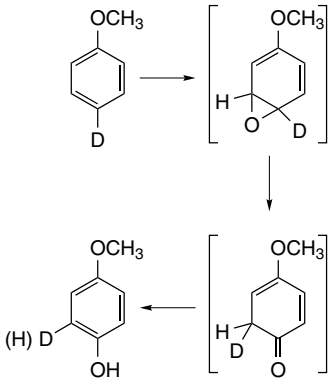

Fig. 2 The cytochrome P450–catalyzed epoxidation of aromatic rings is commonly followed by the "NIH Shift", a nonenzymically catalyzed rearrangement that converts the epoxide to the corresponding phenol.

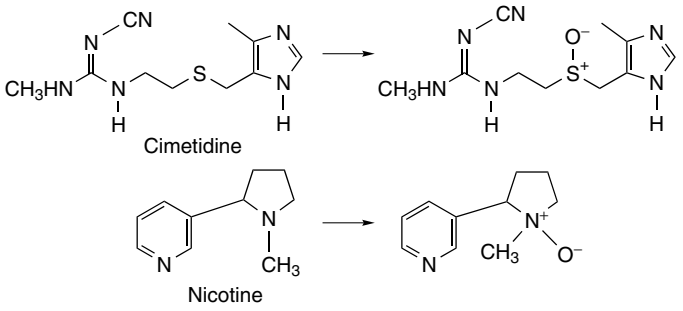

Fig. 3 Cytochrome P450 and the flavin-containing monooxygenase (FMO) catalyze the oxidation of nitrogen and sulfur, as illustrated by the sulfoxidation of cimetidine and the N-oxidation of nicotine.

The flavin-containing monooxygenases, or FMOs, are generally limited to the NADPH- and oxygen-dependent oxidation of nitrogen and sulfur atoms and therefore have a more restricted metabolic scope than cytochrome P450 enzymes. Nevertheless they can play an important role in the metabolism of individual drugs. Both the cytochrome P450 and flavin-containing monooxygenases preferentially oxidize electron-rich heteroatoms.

Cytochrome P450 enzymes can catalyze oxidative reactions other than the three general reactions described above, including reactions such as the dehydrogenation of alkyl groups, deformylation of aldehydes, and cleavage of carbon–carbon bonds. Although relatively rare, these reactions have been more frequently observed in the past few years. Under conditions of low oxygen tension, cytochrome P450 enzymes also catalyze reductive reactions, including the reduction of nitro and azo groups to amines and the dehalogenation of haloalkanes.

3.2 Monoamine Oxidase

Monoamine oxidase is an oxygen-dependent mitochondrial flavoprotein that oxidizes endogenous neurotransmitter amines and related xenobiotics to the corresponding imines. The imines are subsequently hydrolyzed in the aqueous medium to the carbonyl derivatives and either ammonia or an amine, as shown below for 2-phenylethylamine.

$$\mathrm{PhCH_2CH_2NH_2} \longrightarrow \mathrm{PhCH_2CH{=}NH} \longrightarrow \mathrm{PhCH_2CHO + NH_3}$$

Primary amines are particularly good substrates for the enzyme, but secondary amines in which one of the substituents is a methyl or another small alkyl group are readily oxidized. The oxidation of trisubstituted amines often results in inactivation of the enzyme, a phenomenon exploited in the development of clinically useful inhibitors of the monoamine oxidases.

3.3 Alcohol and Aldehyde Dehydrogenases

Alcohol dehydrogenases are members of a family of cytosolic enzymes that catalyze the NAD-dependent oxidation of alcohols to aldehydes or ketones as well as the reverse reaction, the NADH-dependent reduction of carbonyl compounds to alcohols (Fig. 4). At least 16 different alcohol dehydrogenase isoforms have been identified in human liver. Less well characterized

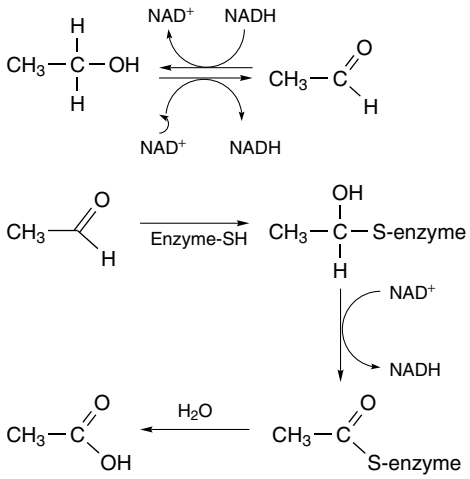

Fig. 4 Alcohol dehydrogenases catalyze the reversible oxidation of alcohols to aldehydes and ketones, as illustrated by the oxidation of ethanol to acetaldehyde. The oxidation of aldehydes to carboxylic acids, such as that of acetaldehyde to acetic acid, is catalyzed by aldehyde dehydrogenases. The aldehyde reacts with a thiol in the aldehyde dehydrogenase to give an enzyme-bound hemithioacetal intermediate that is then oxidized to an enzyme-bound thioester and finally released by hydrolysis of the thioester bond.

aldehyde and ketone reductases that employ NADPH as the reducing cofactor are also involved in the reduction of carbonyl compounds to alcohols. The direction of the reaction catalyzed by alcohol dehydrogenases is dictated by the redox balance of the pyridine nucleotide pool and by whether an alcohol or carbonyl compound is the substrate, although a thermodynamic equilibrium mixture of the alcohol and carbonyl compound would be obtained were it not for the fact that the substrate and product are removed from the solution by alternative metabolic reactions and the dynamic nature of the circulatory and excretory systems.

Aldehydes are primarily oxidized by NAD^+ -dependent aldehyde dehydrogenases (Fig. 4). A molybdenum-containing enzyme related to xanthine oxidase may also contribute to aldehyde oxidation, but its physiological importance in the general metabolism of xenobiotic aldehydes is unclear. Unlike the alcohol dehydrogenases, the aldehyde dehydrogenases do not simply transfer a hydride from the aldehyde substrate to the pyridine nucleotide cofactor. The first step of the reaction is addition of the aldehyde to an active site cysteine thiol to give a hemithioacetal that is then dehydrogenated by a hydride transfer to an enzyme-bound thioester. Hydrolysis of the thioester releases the acid metabolite and regenerates the enzyme (Fig. 4). Because of the complexity of this mechanism, aldehyde dehydrogenases catalyze the oxidation of aldehydes to acids but not the reverse reaction. In effect, carboxylic acids and xenobiotics with functionalities such as amides and esters in which the carbon has a comparable oxidation state are rarely metabolically reduced.

Alcohol and aldehyde dehydrogenases are the primary enzymes involved in the metabolism of ethanol, the former catalyzing the oxidation of ethanol to acetaldehyde and the latter the conversion of acetaldehyde to acetic acid (Fig. 4). The oxidation of ethanol to acetaldehyde can also be mediated by catalase and cytochrome P450, but under normal conditions alcohol dehydrogenases are the principal catalysts for this transformation. Genetic polymorphisms in the levels of both the alcohol and aldehyde dehydrogenases are responsible for the lower tolerance of certain populations to the pharmacological effects of ethanol. Inhibition of acetaldehyde

dehydrogenase by drugs such as disulfiram [$Et_2NC(S)SSC(S)NEt_2$] or by metabolites of other drugs that also give stable adducts with the catalytic thiol group causes hypersensitivity to the noxious effects of ethanol. This property of disulfiram has been exploited in the treatment of chronic alcoholism.

3.4 Esterases and Amidases

The hydrolysis of esters and amides, a very general metabolic pathway, is catalyzed by a diverse group of carboxylesterases. These enzymes differ in their mechanisms and substrate specificities but commonly catalyze ester and amide, as well as thioester, hydrolysis. Many of the carboxylesterases are serine hydrolases in which an active site serine catalyzes the hydrolytic reaction, but enzymes of other types are also involved. Large concentrations of these enzymes are found in the liver and kidney, but they can be found in most tissues. As a rule, ester hydrolysis occurs more rapidly than amide hydrolysis, in accord with the relative susceptibilities of the two functionalities toward chemical hydrolysis.

The carboxylesterases hydrolyze esters to the carboxylic acid and alcohol, and amides to the corresponding carboxylic acid and amine.

$$RCO_2R' \longrightarrow RCO_2H + R'OH$$

$$RCONR'R'' \longrightarrow RCO_2H + R'NHR''$$

Ester and amide hydrolysis greatly increases the polarity of the substrate, as it replaces the neutral ester or amide function with a highly ionized (at pH 7) carboxylic acid group. The amine group released by amide hydrolysis is also likely to be protonated at physiological pH, and the alcohol, albeit not ionized, is likely to be more polar due to the presence of the hydrogen-bonding hydroxyl group. Furthermore, the functionalities unmasked by ester or amide hydrolysis are susceptible to glucuronidation, sulfation, and/or amino acid conjugation (See Sect. 4).

Esterification is often used to convert drugs to prodrugs from which the parent drugs are released metabolically at rates, or in tissue locations, that improve the pharmacokinetic properties and therapeutic activities of the drugs. For example, fluphenazine is a short-lived antipsychotic agent that must be administered several times a day to be effective. Esterification with a short-chain fatty acid, however, yields a derivative that can be administered in a single, relatively large dose that is deposited in adipose tissue. Hydrolytic release of therapeutic doses of fluphenazine from the ester occurs over a period of two to four weeks (Fig. 5).

3.5 Epoxide Hydrolases

The hydrolysis of epoxides is catalyzed by epoxide hydrolases located in both the

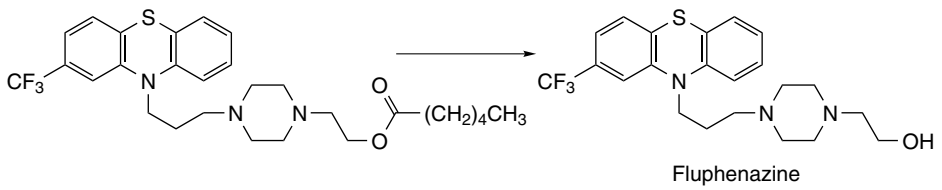

Fig. 5 Fatty acid ester derivatives of fluphenazine are lipophilic prodrugs from which fluphenazine, the active principle, is released by enzymatic hydrolysis.

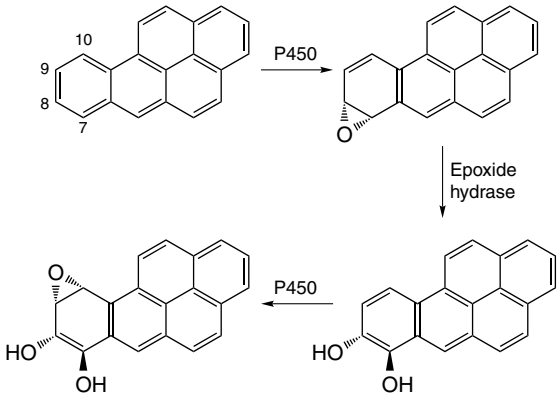

Fig. 6 The epoxidation of benzo[a]pyrene by cytochrome P450 is followed by enzymatic hydrolysis of the epoxide and a second cytochrome P450–catalyzed epoxidation reaction. The resulting highly reactive diol epoxide alkylates DNA and this reaction is at least partially responsible for the carcinogenic properties of this polycyclic aromatic hydrocarbon.

endoplasmic reticulum and the cytosol. The membrane-bound and soluble enzymes have somewhat different substrate specificities, but both formally catalyze backside addition of water to the epoxide to give a trans-diol product. The actual mechanism of the reaction, however, is addition of a carboxylic acid group of the enzyme to the epoxide followed by internal hydrolysis of the resulting protein-bound ester. In general, increasing the number of substituents on the epoxide decreases the rate of enzymatic hydrolysis by the membrane-bound enzyme but has less effect on hydrolysis of the epoxide by the soluble enzyme. Although epoxide groups are usually not found in drugs or xenobiotics because of their chemical reactivity, the ability to detoxify epoxides is very important because epoxides are formed *in situ* by the cytochrome P450–catalyzed oxidation of olefins and aromatic rings (Sect. 3.1). Epoxides are also detoxified by the glutathione transferase–mediated addition of glutathione (Sect. 4.5). The redundancy represented by the abilities of both epoxide hydrolases and glutathione transferases to detoxify epoxides reflects the importance of doing so to the well-being of the host.

Epoxide hydrolysis is normally a detoxifying reaction because it converts chemically reactive epoxides into nonreactive diols that can be glucuronidated or sulfated. Nevertheless, the potential deleterious interplay between cytochrome P450 enzymes and epoxide hydrolases is well illustrated by the bioactivation of carcinogenic polycyclic aromatic hydrocarbons. In the case of benzo[a]pyrene, one of the reaction sequences thought to play an important role in carcinogenesis involves oxidation of the 7,8-double bond of the hydrocarbon by cytochrome P450, hydrolysis of the epoxide to the *trans*-7,8-diol by epoxide hydrolase, and epoxidation of the 9,10-double bond by cytochrome P450 to give the 9,10-epoxy-7,8-diol (Fig. 6). This highly reactive diol epoxide alkylates DNA, causing a lesion that engenders a carcinogenic response.

4
Phase II Enzymes

4.1
Glucuronyl Transferases

Glucuronidation is among the most common and quantitatively most

important pathways of drug and xenobiotic metabolism. The reaction is catalyzed by a family of membrane-bound enzymes known as UDP-glucuronosyltransferases (or glucuronyl transferases). The number of enzymes in this family is not known, but evidence exists for at least a dozen rat enzymes and a corresponding number of human enzymes. UDP-glucuronosyltransferases transfer the glucuronic acid moiety from the endogenous donor uridine-5′-diphospho-α-D-glucuronic acid (UDPGA) to an acceptor function on the drug or xenobiotic (Fig. 7). Glucuronidation greatly increases the polarity and water solubility of most xenobiotics due to the high ratio of oxygen to carbon atoms in glucuronic acid and the fact that its carboxyl group ($pK_a = 3.5$) is highly ionized at physiological pH. This increase in ionic character and polarity greatly accelerates excretion of the xenobiotic. Glucuronidation usually occurs only once and it is the last step in a metabolic sequence because the glucuronide metabolite is usually too polar to interact efficiently with the membrane-bound enzymes of drug metabolism and is readily excreted. A few lipophilic compounds are known, however, that are glucuronidated twice. Bilirubin produced endogenously by the catabolism of heme is one of these compounds.

Glucuronidation involves displacement of the UDP phosphate group by a nucleophile in the xenobiotic. The stereochemistry of the glucuronic acid carbon involved in the reaction is inverted, in accord with a backside displacement mechanism (Fig. 7). The glucuronic acid moiety can be transferred by UDP-glucuronosyltransferases to most nucleophilic groups if they can be deprotonated at physiological pH to accommodate

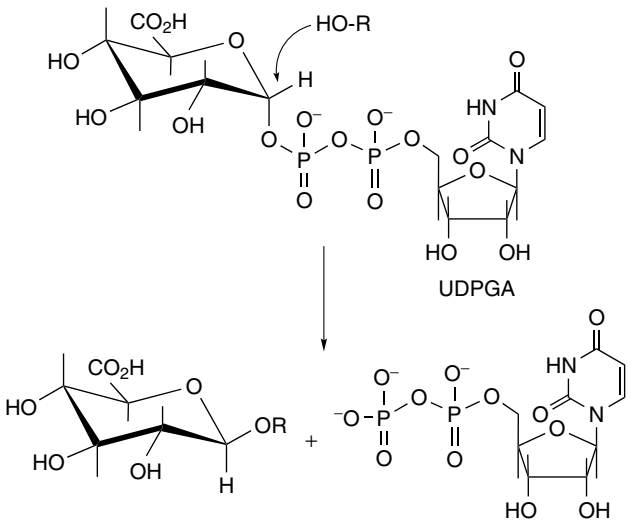

Fig. 7 Glucuronidation by glucuronosyl transferases involves transfer of the glucuronic acid moiety from uridine-5′-diphospho-α-D-glucuronic acid (UDPGA) to the substrate, illustrated here by an alcohol (ROH).

the glucuronic acid moiety. Hydroxyl, carboxyl, amino, and sulfhydryl functions such as those found in phenols, alcohols, enols, carboxylic acids, hydroxylamines, primary amines, and mercaptans are thus commonly glucuronidated. Acetaminophen, clofibrate, and 1-naphthylamine are examples of drugs and xenobiotics that are extensively glucuronidated (Fig. 8).

Trisubstituted amines, nitrogen heterocycles, and a few other nitrogen-containing functionalities are unique in that they can be glucuronidated in the absence of deprotonation to give quaternary, charged products. An example of such a transformation is the glucuronidation of ketotifen (Fig. 8). Carbon glucuronidation is possible with compounds such as phenylbutazone that have highly acidic carbon atoms.

Glucuronyl transferase activity depends on a variety of factors, including age, diet, genetic factors, hormonal status, and cigarette smoking. The increase in glucuronidation observed during the neonatal period is very important because bilirubin, the catabolite of heme, is not readily excreted unless it is first glucuronidated. The low levels of glucuronosyltransferase activity at birth can result in bilirubin accumulation, jaundice, and nervous system damage unless measures (usually phototherapy) are taken to eliminate bilirubin by other mechanisms until the appropriate glucuronosyltransferase increases to the appropriate functional level.

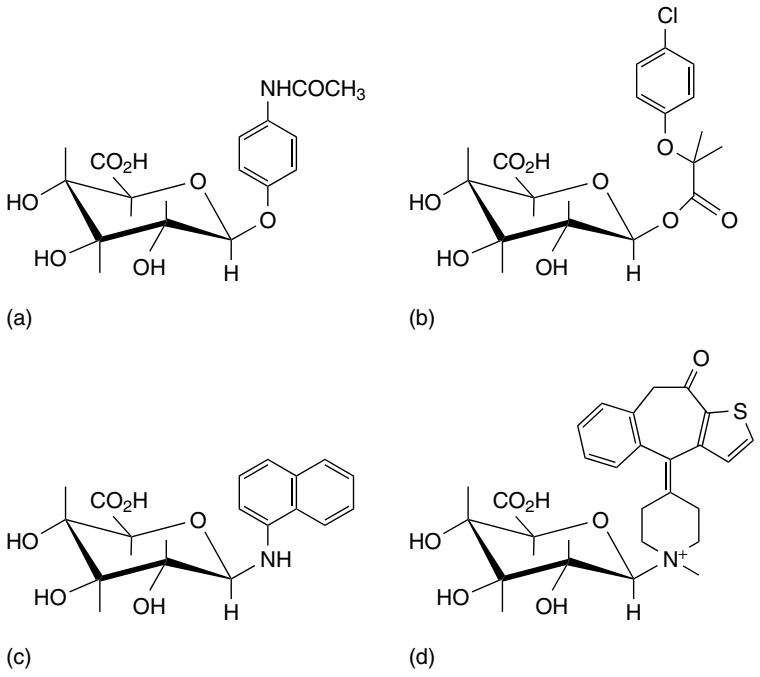

Fig. 8 Examples of glucuronides in which the functionality that is glucuronidated is (a) the phenol group of acetaminophen, (b) the carboxylic acid of clofibrate, (c) the amino group of 1-naphthylamine, and (d) the trisubstituted amine group of ketotifen.

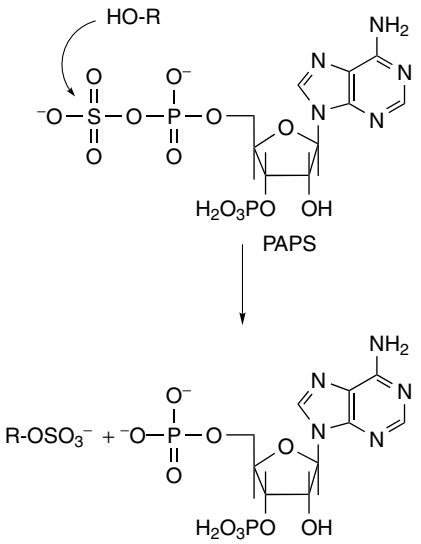

Fig. 9 Sulfation catalyzed by sulfotransferases involves transfer of the sulfate group of 3-phosphoadenosine-5′-phosphosulfate (PAPS) to the substrate, represented in the figure by an alcohol (ROH).

4.2 Sulfotransferases

Sulfotransferases are soluble enzymes that transfer the sulfate group from 3-phosphoadenosine-5′-phosphosulfate to a nucleophile on the drug or xenobiotic (Fig. 9). The pK_a value (~ -7) of the sulfate function is such that the resulting sulfate conjugates are completely ionized, and therefore more readily eliminated, under all physiological conditions. Sulfation of drugs and xenobiotics is almost as common as glucuronidation. The physiological sulfate pool appears to be limited, however, so that the proportional importance of sulfation often decreases as the dose of the drug or xenobiotic increases.

The range of functionalities that undergo sulfation is similar to, but more limited than, the range that undergoes glucuronidation. Hydroxyl groups, particularly phenolic groups such as that in terbutalin (Fig. 10), and amino functions are the most commonly sulfated. The sulfation of carboxylic acids, trialkylamines, and sulfhydryl groups, unlike glucuronidation, is not observed. In the case of sulfhydryl groups, limited evidence suggests that

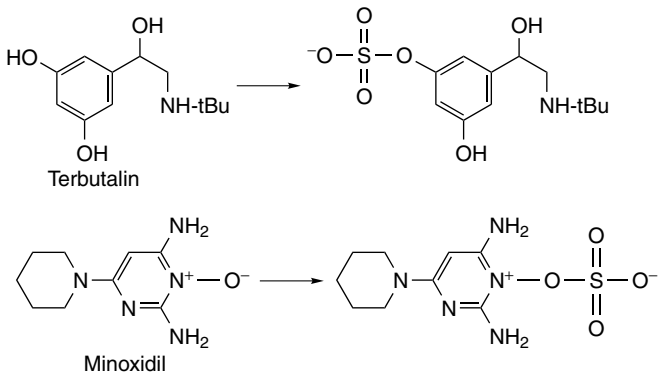

Fig. 10 Sulfation of the phenol function of terbutalin increases its polarity and excretability. Sulfation of the N-oxide group of minoxidil is unusual and produces a metabolite that is responsible for the vasodilatory properties of the drug (actually a prodrug).

sulfate derivatives may be formed but react rapidly with glutathione or other protein sulfhydryls to give disulfide products. Sulfation accelerates xenobiotic excretion but, in a few instances, converts prodrugs to their active form. The best example of this is conversion of the vasodilatory prodrug minoxidil to its physiologically active sulfate metabolite (Fig. 10).

4.3 *N*-Acyl Transferases

N-Acyl transferases are involved in three pathways of xenobiotic metabolism: (1) conjugation of the carboxyl group of xenobiotics to the α-amino group of various amino acids to give amino acid conjugates, (2) acetylation of the amino functions of xenobiotics, and (3) acetylation of the cysteine conjugates produced by the glutathione transferase pathway (Sect. 4.5). In each of these acetylation reactions, the carboxyl group is first activated by enzymatic conversion to the corresponding CoA ester. This reaction is catalyzed by ATP-dependent acid:CoA ligases that are also involved in the formation of medium-length fatty acid CoA esters. For the formation of amino acid conjugates, the carboxyl group of the xenobiotic is activated, whereas acetyl CoA provides the activated carboxyl function for *N*-acetylation of the amino functions in xenobiotics or the α-amino groups of cysteine conjugates (Sect. 4.5). Transfer of the activated acyl moiety from the acyl CoA to the amino group of the acceptor is catalyzed by *N*-acyl transferases.

The most common amino acids involved in the formation of amino acid conjugates in mammals are glycine, glutamine, and taurine, although conjugates with arginine, asparagine, histidine, lysine, and serine are also formed in a species-dependent manner. The *N*-acyl transferases and the enzymes that synthesize the acyl CoA esters belong to enzyme families located primarily in the matrix of liver and kidney mitochondria. The range of xenobiotics susceptible to amino acid conjugation is restricted to compounds with a carboxylic acid function. The reaction is catalyzed by acyl-CoA:amino acid *N*-acyltransferases. The increase in polarity achieved by this transformation is modest because the reaction replaces one carboxylic acid function with another and therefore does not greatly alter the ionization state of the xenobiotic. The conversion of benzoic acid to hippuric acid by conjugation with glycine is a case in point.

$$PhCO_2H \longrightarrow PhCOSCoA \longrightarrow PhCONHCH_2CO_2H$$

The acetyl CoA–dependent acetylation of xenobiotic amino groups is catalyzed by cytosolic *N*-acetyl transferases. In man, one form of the enzyme predominates in the liver and gut and another in extrahepatic tissues. Arylamines and hydrazines are the most commonly *N*-acetylated functions, although the reaction also occurs with sulfonamides, aliphatic amines, and related functions. Typical examples of this process are the *N*-acetylation of isoniazid and sulfamethazine (Fig. 11). Because acetylation decreases rather than increases the polarity of the xenobiotic, it can occur at any stage in the metabolic process.

The ability to *N*-acetylate xenobiotics is polymorphically distributed in the human population and has therapeutic and toxicological consequences. For a given dose of a drug, slow acetylators accumulate higher concentrations of the parent drug than fast acetylators. This can have clinical and pathological consequences if the therapeutic index of the drug is fairly

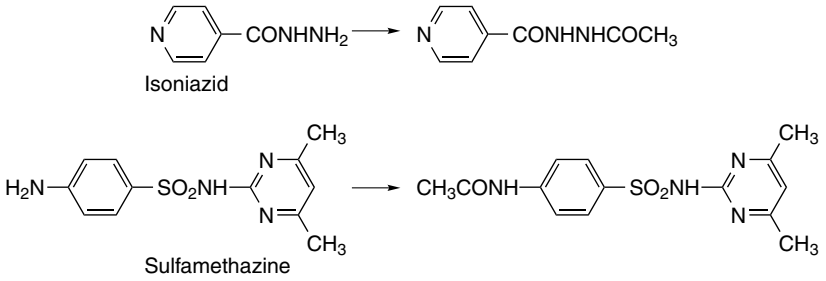

Fig. 11 *N*-Acetylation of a hydrazine (isoniazid) and an aryl amine (sulfamethazine), two typical reactions catalyzed by *N*-acetyl transferases.

narrow. For example, slow acetylators are more susceptible to the peripheral neuropathy associated with isoniazid or the lupus erythematosus side effect of hydralazine. The variability of the *N*-acetylation phenotype in humans is due, at least in part, to point mutations in the *N*-acetyltransferase genes.

4.4 Methyl Transferases

N-, *O*-, and *S*-methylations of xenobiotics are catalyzed by *S*-adenosyl-*L*-methionine-dependent methyltransferases, including enzymes such as catechol *O*-methyltransferase and indolethylamine *N*-methyltransferase, whose primary substrates are endogenous neurotransmitters and their metabolites (Fig. 12). The substrate specificities of these enzymes are broad enough that they often also methylate drugs that have the required functionality and structurally resemble the endogenous substrates. Methylation of the meta-hydroxyl group in a catechol substrate such as dopamine (Fig. 12) is usually favored over methylation of the para-hydroxyl, although both products are formed. One consequence of the fact that the primary function of the *N*- and *O*-methyltransferases is the metabolism of endogenous substrates is that methylation of hydroxyl and amine groups primarily occurs with xenobiotics that structurally resemble endogenous neurotransmitters. A second consequence is that the polarity of the substrate is decreased rather than

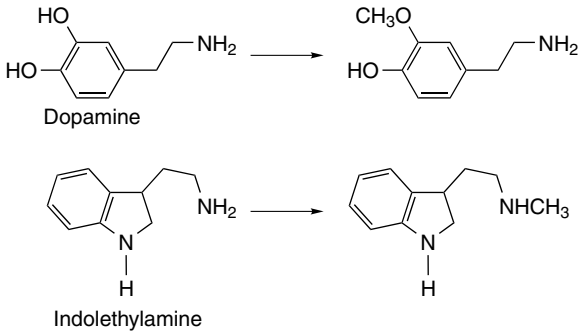

Fig. 12 Methylation of the catechol group of dopamine and the primary amine group of indolethylamine.

increased by methylation. Methylation and *N*-acetylation are therefore the two general pathways that decrease substrate polarity.

4.5 Glutathione Transferases

Glutathione is a tripeptide in which the carboxyl and amino groups of cysteine are linked respectively to a glycine and the γ-carboxyl group of glutamic acid (Fig. 13). Incorporation of cysteine into this tripeptide protects it from utilization in protein synthesis and makes possible the accumulation of high (5–10 mM) concentrations of the cysteine sulfhydryl in tissues. These high concentrations are desirable because glutathione serves as the major line of defense against electrophilic, chemically reactive species, including xenobiotics, xenobiotic metabolites, and reactive oxygen derivatives. Highly reactive electrophilic metabolites can be trapped by direct, uncatalyzed reaction with the glutathione sulfhydryl group, but the addition of glutathione to moderately or weakly electrophilic compounds is catalyzed by a family of enzymes known as glutathione transferases. The glutathione transferases have broad, overlapping substrate specificities and are primarily, but not exclusively, located in the cytosol.

Glutathione reacts chemically or with the catalytic assistance of a glutathione transferase with essentially all electrophilic functionalities, including alkyl and acyl halides (Fig. 13), epoxides (Fig. 14), electrophilically activated aromatic ring systems (Fig. 14), and α,β-unsaturated carbonyl compounds (Fig. 15). The products of the reactions are the thioethers or thioesters in which the cysteine sulfhydryl has added to the electrophilic center, usually with concomitant displacement of a leaving group from the same center. The glutathione transferases promote these reactions, in part, by simply binding the lipophilic, electrophilic substrates in close proximity to the enzyme-bound glutathione.

Glutathione conjugates are usually more polar and/or highly ionized than the parent xenobiotic due to the hydrophilic nature of the tripeptide and the presence of ionizable amino and carboxyl functions in it. Glutathione conjugates are actively transported out of cells, but the conjugates undergo further transformation before they are excreted. Glutamic acid

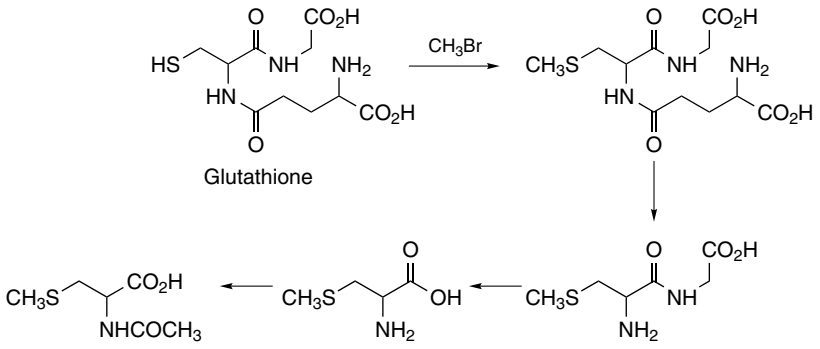

Fig. 13 The sequence of steps involved in conjugation of the tripeptide glutathione with an electrophilic substrate, here methyl bromide, and subsequent processing of the glutathione conjugate to the *N*-acetylcysteine conjugate that is actually excreted.

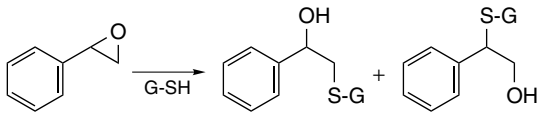

Fig. 14 Addition of glutathione to the epoxide of styrene oxide and the activated aromatic ring of a herbicide. GSH stands for glutathione.

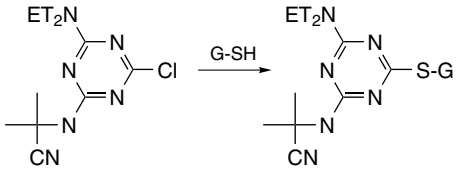

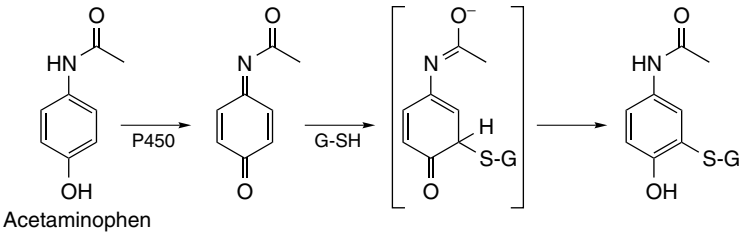

Fig. 15 Acetaminophen is oxidized by cytochrome P450 to a chemically reactive iminoquinone structure that is trapped by glutathione to give a glutathione conjugate. In the absence of glutathione, the iminoquinone alkylates multiple liver proteins.

and glycine are first removed from the conjugate by the ordered, sequential action of a γ-glutamyl transpeptidase and a peptidase (Fig. 13). High concentrations of these enzymes are found in the kidney. The cysteine conjugate obtained by removal of the two protective amino acids is then *N*-acetylated by the action of an acetyl CoA–dependent *N*-acetyltransferase (See Sect. 4.3). *N*-Acetylation converts the zwitterionic amino acid derivative into a simple carboxylic acid and thus prevents reabsorption of the conjugate from the kidney by amino acid transporters. The *N*-acetyl cysteine conjugates, known as mercapturic acids, are generally excreted in the urine.

The cysteine conjugates prior to *N*-acetylation, or regeneration by hydrolysis of the *N*-acetyl group of the mercapturic acid derivatives, are subject to an alternative metabolic pathway initiated by a β-lyase. This pyridoxal phosphate-dependent enzyme catalyzes removal of the proton adjacent to the amino group with concomitant elimination of the thioether or thioester group. The products of the reaction are the sulfhydryl derivatives of the original xenobiotic and pyruvic acid (CH_3COCO_2H) (Fig. 16). The free sulfhydryl group is then methylated by an *S*-adenosyl-*L*-methione-dependent *S*-methyl transferase (See Sect. 4.4). The thiomethyl product is relatively nonpolar and can be oxidized by a cytochrome P450 or flavin-containing monooxygenase to the corresponding sulfoxide.

The high concentrations of glutathione present in most tissues provide a reserve

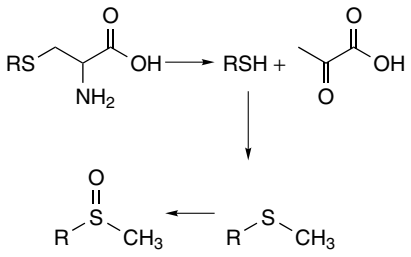

Fig. 16 The cysteine β-lyase pathway for the metabolism of cysteine conjugates derived by normal proteolytic processing of glutathione conjugates. The thiol derivative released from the cysteine conjugate by the action of cysteine β-lyase can be methylated by an *S*-methyltransferase and subsequently oxidized to the sulfoxide by a monooxygenase.

for the detoxification of reactive, electrophilic compounds. This reserve is nevertheless limited and exposure to large amounts of electrophilic species can result in its temporary depletion. Depletion of the glutathione reservoir in the face of continued exposure to electrophilic products can result in life-threatening cell and organ damage. The relationship between glutathione depletion and cell damage has been most extensively studied with acetaminophen, a small fraction of which is oxidized by cytochrome P450 to a highly reactive iminoquinone derivative that is normally detoxified by glutathione (Fig. 15). The protection provided by glutathione is such that normal doses of this over-the-counter analgesic agent are nontoxic. Ingestion of large doses of acetaminophen, however, results in the formation of sufficiently large amounts of the reactive metabolite that the glutathione reservoir is depleted. The iminoquinone metabolite is then free to react with cellular constituents, causing hepatic necrosis and, if the damage is sufficiently extensive, death. The same toxic consequences are observed but at a lower dose of acetaminophen if the glutathione concentration is first depleted by administration of a second agent or if the proportion of the reactive metabolite is increased by induction of the appropriate cytochrome P450 enzyme.

5 Xenobiotic Metabolism and Toxicity

The low reaction control implicit in the broad specificity of drug-metabolizing enzymes and the unpredictable diversity of xenobiotic structures make drug metabolism a major contributor to the toxicity and carcinogenicity of xenobiotics. For example, the cytochrome P450–catalyzed oxidation of aflatoxin and polycyclic aromatic hydrocarbons to epoxides (Fig. 6) that bind covalently to DNA is directly responsible for the carcinogenic properties of these substances. The analogous covalent binding of reactive metabolites to proteins is responsible for the toxic properties of many xenobiotics. Thus, the oxidation of allyl alcohol by alcohol dehydrogenases produces acrylaldehyde ($CH_2{=}CHCH_2OH \rightarrow CH_2{=}CH{-}CH{=}O$), a reactive electrophilic agent that alkylates proteins and causes tissue damage. As noted in Sect. 4.4, a major role of the glutathione system is to prevent tissue damage by trapping metabolically produced reactive species. The relationship between the glutathione system and toxicity has been most clearly defined in the case of acetaminophen. Thus, the metabolism of lipophilic compounds is essential for their elimination but not infrequently produces species of higher toxicity than the parent structure.

6
Therapeutic Aspects of Drug Metabolism

The magnitude and duration of drug action is controlled by the extent and rate of absorption of the drug, the extent and rate at which it is delivered to the target site, the extent and rate of its metabolism, and the rate at which it is cleared from the body. Factors that influence the role of metabolism in determining drug action include exposure to other drugs or xenobiotics, genetic makeup, gender, diet, age, and alterations in physiological status. Concomitant exposure to a second xenobiotic can increase the metabolism of a compound by enzyme induction or decrease its metabolism by enzyme inhibition. For example, phenobarbital increases the metabolism of phenytoin when both are used in the treatment of epilepsy by inducing cytochrome P450 isoforms that oxidize phenytoin.

The genetic makeup of the individual is important because the levels of individual drug-metabolizing enzymes in the human population are genetically determined. Gender and physiological status are important because hormonal factors alter, among other parameters, the levels and types of drug-metabolizing enzymes. The profile of drug-metabolizing enzymes is thus determined by a combination of heredity and environment and varies from individual to individual.

7
Species Differences and Extrapolation to Humans

In view of the sensitivity of drug-metabolizing systems to genetic and environmental factors, it is not surprising that there are major differences in the metabolism of xenobiotics by different species. The species-dependence of drug metabolism is a major concern in the extrapolation to humans of metabolic, pharmacokinetic, and toxicological data obtained with animals. Interspecies variability involves xenobiotic absorption, distribution, and excretion as well as metabolism. Unfortunately, no single animal is a reliable mimic of drug metabolism in humans, although on the average the rhesus monkey is probably one of the better mimics. For example, glucuronidation is a negligible metabolic pathway for oxaprozin in rats, but accounts for roughly half of the total metabolic products in rhesus monkeys and man (Fig. 17). It is not uncommon, however, for other species to predict the metabolism of specific xenobiotics via individual pathways

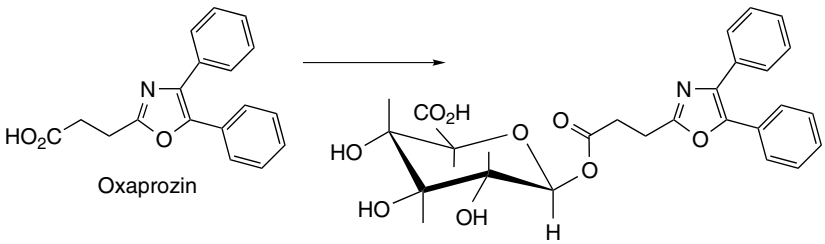

Fig. 17 Glucuronidation of oxaprozin is a major pathway of metabolism in humans and rhesus monkeys but not in rats.

better than the rhesus monkey. The extrapolation and scaling of drug metabolism data from animals to humans, despite its practical importance, is therefore still a difficult and imprecise science.

8
High-throughput Methods in Drug Metabolism Studies

The acceleration of lead candidate discovery by combinatorial synthesis and high-throughput screening methods, combined with the realization that metabolism and pharmacokinetics are critical determinants of a candidate's success, has led to efforts to develop methods that allow a large number of drug candidates to be screened for metabolic properties at an early stage of the drug discovery process. The properties of greatest interest are absorption, metabolism, and the inhibition and induction of individual cytochrome P450 enzymes. The approaches being pursued include computational methods for the prediction of probable metabolic profiles, *in vitro* studies of metabolic stability, reporter constructs in which the activation of receptors responsible for the induction of specific cytochrome P450 enzymes is readily visualized, DNA and protein microarray analysis of changes in metabolic enzyme levels, and high-throughput mass spectrometric approaches to determining actual metabolite profiles.

Oligonucleotide Probe Design 84

Keywords

Gene
A part of genome, which is coded for proteins or templates of many functional RNAs.

Genome
A set of genes, which are required for a particular organism.

Gene Expression
A process in which DNA of a gene is transcribed into RNA, and then translated into protein.

Alignment Algorithm
A computer algorithm used to compare multiple nucleotide or amino acid sequences.

SNP Classification
A classification that is necessary because current single nucleotide polymorphism (SNP) data tend to have errors.

EST Orientation
EST sequences can be aligned onto genomic DNA according to which strand of the genomic DNA is transcribed.

Oligomer Design
Oligo-nucleotide whose sequence is unique within the particular genome is useful for various purposes, for example, designing of DNA-chip.

One of the major objectives of the Human Genome Project (HGP) was to list the entire set of genes and their functions together with control mechanisms written in the human genome. Thus, genome-wide mRNA/cDNA analyses were conducted at about the same time as the major research topic of the Human Genome Project. The first approach was to compile a complete catalog of genes written in the genome of particular organisms, such as human or mouse, through a random collection of expressed cDNA sequences (expressed-sequence tags, ESTs). The second approach has more focus on the status of expressed genes through the acquisition of expression profiles of mRNA/cDNA (body mapping) isolated from a particular cell group, tissue, or organ. Much of the EST approach, such as the gene cataloguing project,

is qualitative. In contrast, body-mapping projects are designed to clarify the differences of cells or tissues in terms of gene expression profiles; thus, they have to be quantitative at every step during the experiment. Integration of millions of EST alignments on the human genome needs browsers that facilitate efficient searching and browsing of an enormous quantity of EST alignments. To achieve this goal, it is essential to meet specific computational requirements, such as the acceleration of sensitive-but-slow (dynamic programming) alignment algorithms, and the resolution of EST orientations. Genome browsers such as Ensembl, UCSC, NCBI, and GRL support these functions.

1 Overview

Nearly two years after the publication of the historic paper on the human draft genome sequence and initial analyses, sequencing of most of the euchromatin region of the human genome is near completion, ushering in the age of genome science (announcement of the completion of human genome was made in April 2003). The complete sequence of the human genome or any genome will provide researchers and the society with valuable information concerning the positions and primary structures of genes, genetic markers, repetitive sequences, functional elements, and lines of evidence of chromosomal rearrangement during human evolution. Many of these aspects are, at present, incompletely understood, and await intensive studies in the future by scientists from various disciplines. Structural analyses of other functionally important elements, such as centromeric and telomeric regions that are buried in heterochromatin must wait for a longer period. In addition, the sequences and position data will be updated for many years.

However, the sequence we will see in a database of a human genome is a sort of patchwork of several genomes because of the technical considerations relating to the sequencing and preparation of DNA materials. Thus, the sequence in the public databases (GenBank, DDBJ, and EMBL) should be regarded as a reference set for our genome. It is very important, when we look at the sequence data, that we keep in mind that the human genome does not reflect the heterogeneity of human population. Because of this, variation studies, such as identification of Single nucleotide polymorphisms (SNPs) and typing of haplotype patterns using various human subpopulations will be important to identify the functional differences linked with specific genomic variation. In other words, functional studies of personal differences will be the basis of the medical and pharmaceutical studies in the future.

In this chapter, a set of databases and tools that we believe will be useful to such studies will be presented. Statistical and mapping data presented in the later section of this chapter are calculated using human genome assembly data available in January 2003.

1.1 Genes and Genome

One of the major objectives of the Human Genome Project (HGP) was to list

the entire set of genes and their functions together with control mechanisms written in the human genome. However, thanks to the progress of recent molecular biology/genetics over the past decade, we now know that genes are not mere stretches of nucleotides but are dynamically controlled, depending on, for example, the developmental stages, and the conditions of the outer environments of cells or organisms. Thus, genome-wide mRNA/cDNA analyses were conducted at about the same time as the major research topic of the Human Genome Project.

Several different approaches have been tested and are still in use for these purposes. The first approach was to compile a complete catalog of genes written in the genome of particular organisms such as human or mouse through a random collection of expressed cDNA sequences (expressed-sequence tags, ESTs) from various tissues. Once as many of these as possible have been collected, computational methods involving clustering were used to compile each of the cDNA fragments into groups of mRNA sequences, based on their sequence similarities. In other words, the final goal of this kind of approach is to make a list of entire genes and their genomic localizations linked with annotated databases. Recent development of a high-throughput computational approach is discussed in the later part of this chapter.

The second approach has more focus on the status of expressed genes through the acquisition of expression profiles of mRNA/cDNA (body mapping) isolated from a particular cell group, tissue, or organ. Human body mapping was first started using quantitatively prepared cDNA libraries constructed from mRNA isolated from anatomically purified cells or tissues through microscopic dissection, cell culture, and other cell purification technologies (Fig. 1). For the experimental details of body mapping, refer to the previous edition of this encyclopedia. An alternative approach to determine the expression profiles is SAGE and DNA microarrays that will be discussed in other chapters.

Expression profiling is the only practical approach to quantify the extent and to characterize the specificities of gene expression in a particular cell at a specific time, through the identification of gene signature, elements of gene expression control, and the network of gene

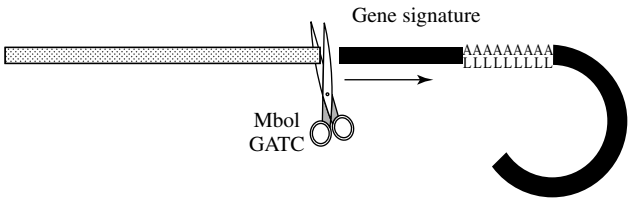

Fig. 1 Libraries and data collection: All libraries used, harbor only the 3′-terminal cDNA fragments made by digesting vector-primed cDNA molecules with *Mbo*I (GATC) in order to facilitate the 3′-EST collection and to minimize the difference in cloning efficiencies among transcripts of different sizes. They were not subjected to amplification, prescreening, or normalization. Accordingly, the clonal recurrence roughly represents transcript abundance in this library.

functions. Altogether, combined with genomic sequences, we will understand the exact mechanisms and signals of gene expression control written in genomic DNA in the near future through experimental data obtained from such studies.

1.2 Body-Map Data

Much of the EST approach, such as the gene cataloguing project, is qualitative. In contrast, body-mapping projects are designed to clarify the differences of cells or tissues in terms of gene expression profiles; thus, they have to be quantitative at every step during the experiment. In general, the following points have to be considered very carefully when carrying out an expression-profiling experiment or interpreting the experimental data obtained from such projects. First, it is important to know the origin and quality of the tissue or cells from which cDNA libraries are prepared. This is especially important when comparing data obtained from different mRNA sources such as tissues, organs, individuals, or species. Secondly, the quality and complexity of the cDNA library have to be carefully examined. Thirdly, any sampling procedure potentially has biases that will severely affect the composition of the final dataset. Without these precautions and evaluation of starting materials and experimental steps, the data will lead to improper conclusions. Statistical assessment of the data as well as the linearity of measuring technology are also important, especially when using fluorescently labeled material because both body mapping and DNA chip technology have experimental characteristics that users have to be aware of when interpreting the final data.

2 Integration of Millions of EST Alignments on the Human Genome

Before the human draft genome became available, ESTs were classified primarily on the basis of sequence similarities. UniGene, for example, employs this method to produce clusters of ESTs. In contrast, the advent of the draft human genome sequence makes it possible to align millions of ESTs with the genomic sequence. Integration of these alignments is helpful in identifying groups of ESTs that are coded at the same locus, in gathering information on alternatively spliced transcripts and their representatives (see Fig. 2), and in associating gene expression patterns with specific loci. It is noteworthy that these two approaches are likely to output different clusters for ESTs that have low-level sequence similarities. This is because the traditional sequence-similarity approach tends to overlook a typical cluster of alignments that share a small number of exons at the same positions.

2.1 Association of Gene Expression Patterns with EST Groups on the Human Genome

Correlation of expression patterns with loci of gene clusters is a crucial step in functional analysis. In an effort to achieve this task, one can attempt to align ESTs associated with gene expression patterns in various tissues with the human genome. For instance, the expression levels of BodyMap representative genes in 30 distinct human tissues are available. BodyMap sequences are hundreds of base pairs in length and are therefore sufficiently long to locate their positions in the human genome. This makes it possible

Fig. 2 Identification of alternatively spliced transcripts and their representatives: there are millions of redundant EST alignments, because it is possible for several distinct ESTs to map to the same locus. In this case, alignments that share common exons on the same strand should be placed in the same group. In the figure, all of the EST sequences are aligned in the 5′ to 3′ direction and displayed from left to right. Each thick line represents the alignment of one EST, in which the narrow yellow boxes are exons, orange boxes are protein coding regions, and the brown boxes are introns. (See color plate p. xxi.)

to annotate about 10 500 EST loci with BodyMap gene expressions.

2.2 Identification of Alternative Splice Forms

Integration of millions of EST alignments enables us to collect alternatively spliced transcripts and their representatives. Figure 2 illustrates a group of alignments in which the second line from the bottom represents the EST alignment of the RefSeq sequence (TAC1, NM_003182) that contains seven exons, while some alternatively spliced transcripts do not use the fourth and sixth exons. Since the protein-coding region (CDS) in the second-from-bottom alignment starts with the second exon and ends with the last (seventh) exon, the bottom alignment, which skips the sixth exon, actually encodes a different protein than the second-from-bottom alignment. Similarly, the third- and fourth-from-bottom alignments do encode distinct proteins.

2.3 Data Cleansing and SNP Classification

Single nucleotide polymorphisms, DNA sequence variations among individuals, have been collected and are stored in databases such as dbSNP (http://www.ncbi.nlm.nih.gov/SNP) and Japanese SNP (http://snp.ims.u-tokyo.ac.jp/). The entry of each SNP involves two sequences that are located before and after the SNP nucleotide, for the identification of the SNP nucleotide, thereby demanding the alignments of the two sequences with the human genome specify the unique location of the SNP nucleotide. Thus, selection of those sequences that map with at least 99% identity to a unique location in the draft genome is effective in eliminating the incorrect SNPs. Furthermore, integration of millions of EST alignments is helpful in classifying the aligned SNPs as regulatory, coding, or noncoding, according to their locations.

3 Computational Methods

Integration of millions of EST alignments on the human genome needs browsers that facilitate efficient searching and browsing of an enormous quantity of EST alignments. To achieve this goal, it is essential to meet specific computational requirements, such as the acceleration of sensitive-but-slow (dynamic programming) alignment algorithms, and the resolution of EST orientations.

3.1 Query into Database of EST Alignments

Since millions of EST alignments with the huge human genome constitute a very large database, various ways to access alignments are indispensable to obtain valuable information. For instance, in a positional cloning project for hunting a human disease gene, if some linkage data suggest that the gene of interest lies between two sequence-tagged site markers, it is informative to enumerate all the known genes and the single nucleotide polymorphisms in the interval between the two markers. It would then follow the precise analysis of alternatively spliced transcripts or individual SNPs that fall within the coding region of a gene. Furthermore, association of a BodyMap sequence with the coding region provides the expression levels of 30 distinct human tissues as supplementary information. These tasks are comfortably facilitated by devising query and search functions in the database that accepts the STS marker name, the GenBank accession number, the RefSeq symbol name, the BodyMap GS number, or the raw sequence of nucleotides of interest. It is also helpful to provide a graphical interface that is capable of browsing genes in one chromosome or in one BAC contig, the exon/intron structure of alternatively spliced transcripts, and the exact positions of SNPs by zooming in and out of the map smoothly and seamlessly. Genome browsers such as Ensembl, UCSC, NCBI, and GRL partly support these functions.

3.2 Efficient Computational Alignment of ESTs with the Human Genome

Here, we briefly mention the key ideas relating to efficient and complex computational methods to align four million ESTs to a newly revised draft genome in just one day. Figure 3 depicts an efficient way of processing millions of ESTs in a reasonable amount of time while retaining sensitivity. The algorithm consists of three key steps. The first step is to build an index lookup table (hash table) of the positions of all the nucleotide sequences of length N (called N-mers) in the DNA sequence. The index aids in locating a single N-mer, say 8mers, instantly, and this represents a crucial step in accelerating the overall performance of mapping millions of ESTs in the genome. The second step is to approximate the start and end positions of each EST alignment by mapping, for instance, 12mers at each end of an EST, which is illustrated in the upper part of the figure. The algorithm scans the EST from

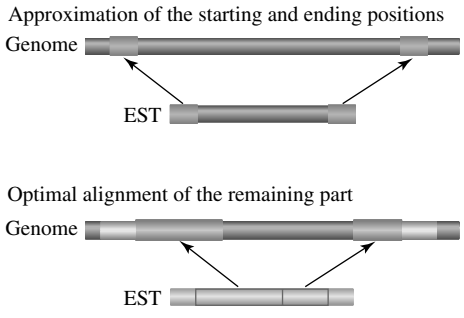

Fig. 3 Accelerated dynamic programming of EST alignments using an index lookup.

the 5′-end until it finds one 12mers that fully matches to the genome; some 12mers are not immediately evident because of errors in the EST sequences. Similarly, the algorithm scans the EST from the 3′-end. The third step is to align the intervening sequence, that is, the sequence between the 12mers at the start and end. The lower part of the figure illustrates a special case, in which our algorithm fractionates an EST into two exons and aligns the exons to the DNA sequence. This method is generally capable of processing ESTs that have more than two exons or intronless ESTs. In situations in which there are multiple potential candidates at the start and end positions, the intervening sequences are investigated with every combination of ends. At the intron boundaries between two exons, it is necessary to move the windows of the two exons so that the exon/intron junctions obey the so-called ''GT. . .AG'' rule.

3.3
Resolution of EST Orientations by Alignments

Individual ESTs are aligned against both the plus and minus strands of the genome. However, even if an EST is aligned to one strand, the EST might actually be read from the other strand. To resolve EST orientation, considering the combinations of EST alignments on genome is effective. The standard test would be to check whether the EST contained poly-A stretches or polyadenylation signals. The existence of a poly-T subsequence at the beginning of an EST indicates that the sequence should be reversed and then complemented to achieve the correct orientation. However, this check does not always work, since the 3′-end sequences are lacking for many ESTs. Another useful rule of thumb is to look at the introns of each EST alignment and to infer the orientation by utilizing the ''GT. . .AG'' rule. For example, if the intron boundary is ''CT. . .AC,'' the alignment needs to be reversed and complemented. However, these two rules are not able to identify the frequently encountered, intronless EST alignments that have neither poly-A stretches nor polyadenylation signals. In this case, it is necessary to see whether the alignment overlaps another EST alignment whose strand orientation has been already confirmed, thereby allowing one to assign the ambiguous EST alignment to the confirmed strand.

4
Use of Human Genome for Observing Gene Expression Patterns

Sequences such as cDNAs, mRNAs, ESTs, and partial fragments of human genome have been the primary sources of designing primers and oligomers for observing gene expression patterns before the elucidation of human genome. Because the human genome involves all the sequence information, full utilization of the human genome may yield novel methods useful in designing primers and oligomers.

4.1
Identification of Less-frequent Subsequences

Traditional methods of primer design make it difficult to select primers that hybridize at only one position. Although RepBase encompasses well-known repetitive sequences, such as Alu, LTR, and LINE, its coverage of less-frequent repetitive sequences is incomplete. Fortunately,

the use of entire genomic sequences appears to offer an effective solution to these problems, because subsequences that appear at extremely low frequencies in the genome would be good primers. Thus, the number of occurrences (frequency) of a subsequence of length N (an N-mer) would serve as a criterion to assess subsequence uniqueness. Subsequently, our primary interest is to list N-mers that appear only once in the genome, that is, unique N-mers. The number of unique N-mers in human genome expands as N increases, but the number converges once N exceeds 18. There are about 1.7 billion unique 18mers, indicating that unique 18mers make up approximately half of all the 3 billion 18mers, and efficiently cover the entire human genome.

4.2 Selection of Oligomers, and Genome Markers

As mentioned above, to evaluate the specificity of primers about 20-nucleotides long, the first step is to determine how frequently they occur. However, for longer oligomers or genome markers of about 50 nucleotides, determination of their frequencies is not useful because the frequencies are usually 1. A more suitable procedure would be to consider the mismatch tolerance of an oligomer, that is, the minimum number of mismatches that allow a given oligomer to match a subsequence other than the target sequence anywhere in the genome. Although calculating the exact value of mismatch tolerance is computationally costly and impractical, it becomes feasible to check if an oligomer meets the relaxed constraint that its mismatch tolerance is no less than a given threshold.

Keywords

Neural induction
The first step involved in forming neural tissue.

Early patterning
Steps involved in dividing neural tissue along the A–P and D–V axes.

Differentiation
Generation of distinct types of cells and/or cellular organization (e.g. nuclei, layers, and so on) in the patterned tissue.

Wiring
Formation of cell processes and connections into functional neuronal circuits.

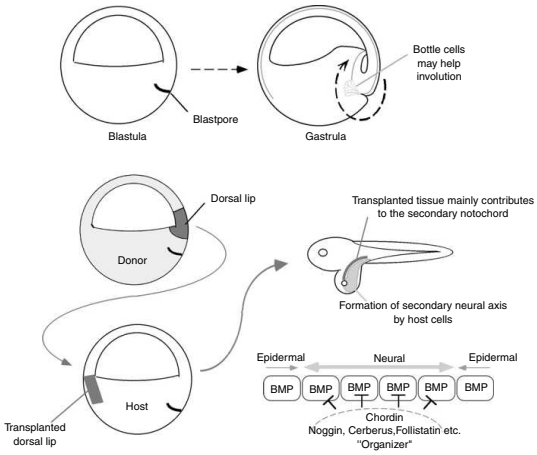
The human brain is an intricate organ with over a hundred billion cells. Brain activity is precisely coordinated to generate electrical and hormonal signals that control basic body functions, movement, awareness, and behaviors. Intriguingly, the incredible complexity of the brain is formed from a simple cellular sheet called the *neural plate*. A progressive series of precisely controlled morphogenetic movements, in combination with cell proliferation, differentiation, and specification of regional character, generates functionally distinct brain structures. In this article, I summarize some of the crucial events happening at the cellular and molecular levels during neural development to help understand the complex processes implicated in vertebrate brain organization.

1 Neural Induction – The First Step Involved in Forming Neural Tissue

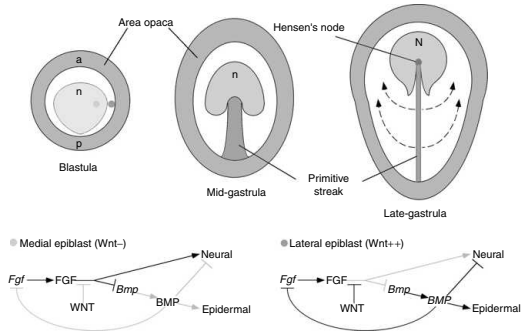
One of the most important events that occur during early vertebrate embryogenesis is *gastrulation*, by which all the three germ layers; *ectoderm, mesoderm*, and *endoderm* are first established. Neural tissue is formed in the ectodermal layer overlying the mesodermal tissue. In 1924, Spemann and Mangold demonstrated that during early gastrulation a distinct population of cells around the dorsal lip in amphibian embryos had the ability to induce an additional head and trunk if grafted into the opposite site of the dorsal lip (i.e. presumptive epidermis) of a host embryo (Fig. 1a). Notable was the fact that the cells in the newly formed head and/or trunk structures were totally derived from the host embryo, indicating that the grafted tissue had an instructive role in organizing the head and trunk tissues. The cells that harbored the ability to induce the secondary axis in the embryo were named *organizer*. The organizer tissue in their experiment had the ability to pattern the mesoderm, including the *notochord* (Fig. 1a). Similar organizer regions have been shown to have a role in the formation and patterning of the axial mesoderm in various organisms, and these regions indeed induce additional neural tissues/axes in developing embryos. Collectively, such processes are termed *neural induction*. While Spemann and colleagues proposed that distinct tissues appear to induce either anterior or posterior characters in the neural tissue of amphibian embryos, Nieuwkoop later suggested a two-step model. In this case, an early activating signal induces neural tissue with an anterior character (i.e. forebrain), and a second posteriorizing or transforming signal that converts neural tissues into a more posterior character further produces regional differences along the axis (i.e. hindbrain and spinal cord). Both classical models that explain frog neural induction involve a degree of neural patterning as very early events. In mice, three distinct tissues, the early gastrula organizer (EGO), anterior visceral endoderm (AVE), and anterior epiblasts, have been implicated in playing a critical role in the induction of anterior neural structures during early gastrulation stages (Fig. 1c). EGO is a cell population in the early primitive-streak stage of the embryo, which displays the cellular properties typical of Spemann's frog organizer. The transplanted EGO/node region indeed has the ability to induce the secondary axis with posterior neural characters, but the AVE as well as the anterior epiblast are further required to induce complete sets of anterior neural structures in mouse embryos, indicating that multiple signaling mechanisms should be involved in neural induction events to simultaneously generate regional differences along the Anterior–Posterior (A–P) axis. I will come back to this point later (Sect. 2,on A–P patterning).

Basic molecular mechanisms involved in neural induction appear to be conserved among vertebrates and invertebrates, although tissue organization of the three germ layers varies from species to species. Key molecules determining neural and nonneural tissues are a signaling factor, Decapentaplegic (Dpp)/bone morphogenetic protein (BMP), and its antagonist secreted from the axial mesoderm, Shorted gastrulation (Sog)/Chordin. BMP signaling participates in the process that converts cells into surface ectoderm (skin), and cells in which the Dpp/BMP signal is antagonized by Sog/Chordin inhibitors are fated to form neural tissue (Fig. 1a). It is now known, however, that vertebrate neural

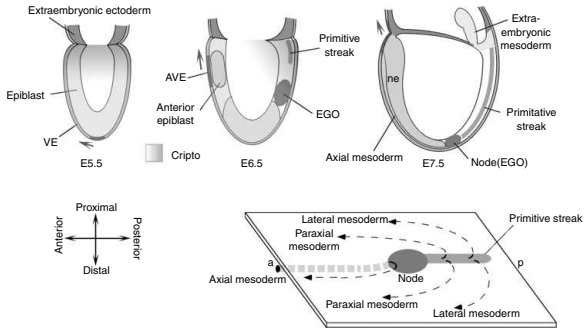
tissue can be generated by the serial inductive actions of surrounding tissues prior to gastrulation without the organizer and/or axial mesoderm signals. For example, even surgical ablations of the notochord as well as genetic manipulations to mutate genes expressed in the organizer, that harbors a role in the formation of the notochord, result in neural tissue formation. Recently, using early chicken embryos as a good



(a) Amphibian



(b) Chicken



(c) Mouse

model system, signaling machineries involved in neural induction were examined, and a new genetic cascade has been proposed (Fig. 1b). According to the hypothesis, a balance of Wnt (see Fig. 2b) and FGF (fibroblast growth factor) signaling pathways is the most critical aspect of neural induction at earlier stages (Fig. 1b). The BMP signaling that finally determines the neural tissue is well-incorporated in this model, yet it remains elusive to what degree this hypothesis can explain the intricate machineries required to establish neural tissue among various vertebrate species.

2 Early Patterning of the Neural Tissue Along the A–P and D–V Axes

Neural induction events determine the definitive area of future neural tissue within the single-layered ectoderm, termed *neuroectoderm*. The neuroectoderm consists of tall epithelial cells and is recognizable as a sheet or plate. All complex structures of the brain emerge from this single-layered cellular sheet termed the *neural plate* (Fig. 3a). Importantly, the neural plate has been exposed to different environments along the A–P and dorsal–ventral (D–V) axes in the embryo. This allows the neural plate to further adopt distinct features in the central nervous system (CNS). I next outline early patterning events in the neural plate along the A–P and D–V axes.

2.1 D–V Patterning in the Neural Plate/Tube

The neural plate rolls up, detaches from the nonneural ectoderm, and finally zips along the dorsal midline of the embryo to form a tubelike structure, called the *neural tube* (Fig. 3a). The D–V axis in the

Fig. 1 Gastrulation and neural induction in various vertebrate species. (a) Gastrulation and neural induction in an amphibian embryo. During gastrulation, bottle cells are observed around the blastpore, allowing the involution of cells (a dotted arrow). Amphibian neural induction events appear to be very dependent upon BMP (bone morphogenetic protein) signaling inhibition, in which BMP antagonists such as Chordin, Noggin, Cerberus, Follistatin, and so on secreted from the organizer play crucial roles. Regarding BMP signaling machineries, see Fig. 2(a) as BMP is a member of the TGF-β superfamily. (b) Gastrulation and neural induction in chicken embryo. During gastrulation, mesodermal cells detach from the epiblast layer and emigrate anterior-laterally (dotted arrows), forming the primitive streak. In the latest model, chicken neural tissue can be formed by FGF and Wnt signals earlier than gastrulation: At the blastula stage, only lateral epiblast (green) expresses Wnt3A/8C, demarcating medial epiblast as the prospective neural tissue (light pink region). The Wnt receptor, Frizzled8, is ubiquitously expressed by all epiblasts at this stage (regarding the Wnt signaling pathway, see Fig. 2(b)). a, anterior; N, neural tissue; n, future neural tissue, p, posterior. (c) Gastrulation, neural induction, and early anterior–posterior axis formation during mouse development. Blue arrows indicate the crucial movement of cells in the endodermal layer, determining anterior characters of the neuroectoderm. Expression of the secreted molecule, Cripto, is dynamically regulated at earlier stages, and this is thought to be critical to initiate A–P patterning events, including the endodermal cell movement as well as primitive-streak formation (purple region). During gastrulation, mesodermal cells detach from the epiblast layer (light green region) and emigrate just like those in the chicken embryo (dotted arrows). a, anterior; AVE, anterior visceral endoderm (dark blue region); E, embryonic day; EGO, early gastrula organizer (red region); ne, neuroectoderm (pink region); p, posterior; VE, visceral endoderm (light blue region). The light gray shading indicates Cripto expression, and the axial mesoderm is colored by orange. (See color plate p. xxii).

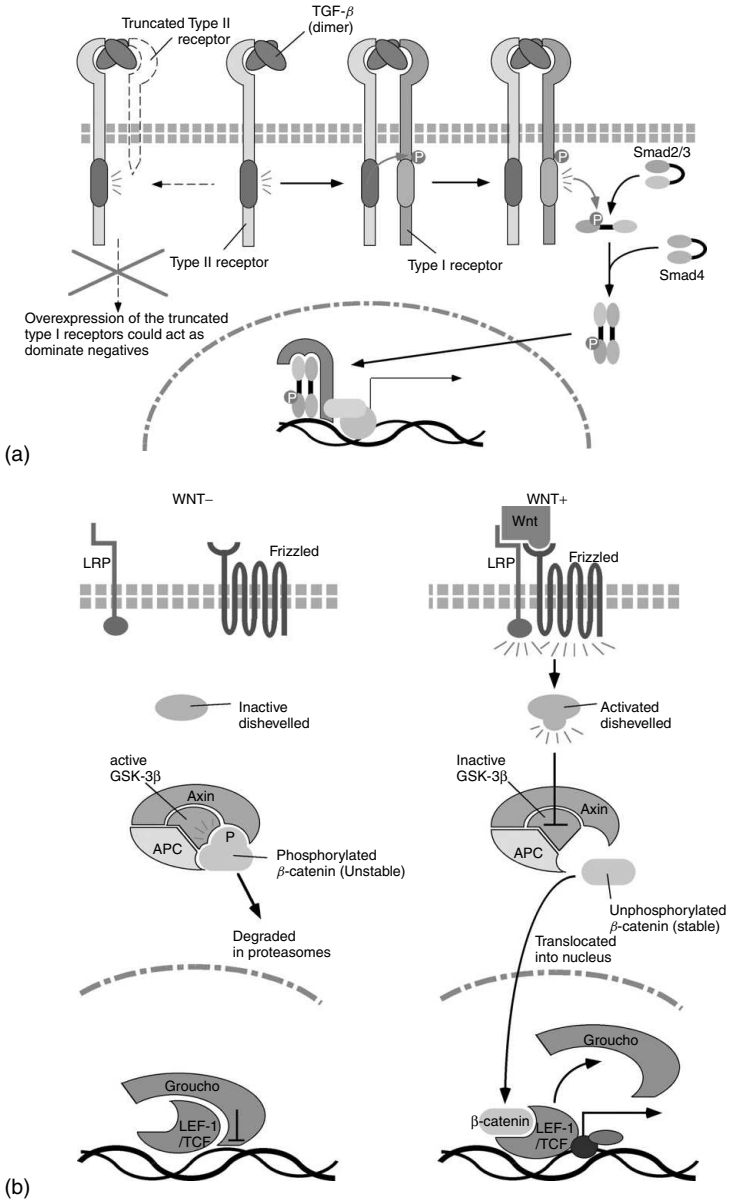


Fig. 2 (a) TGF-β signaling machineries. (b) The canonical Wnt signaling pathway.

neural tube therefore corresponds to the mediolateral axis in the early neural plate: both lateral ends of the neural plate, named the *neural ridge*, become the dorsalmost portion of the neural tube, while the midline of the neural plate, which overlies the axial mesoderm notochord, becomes the ventralmost portion of the neural

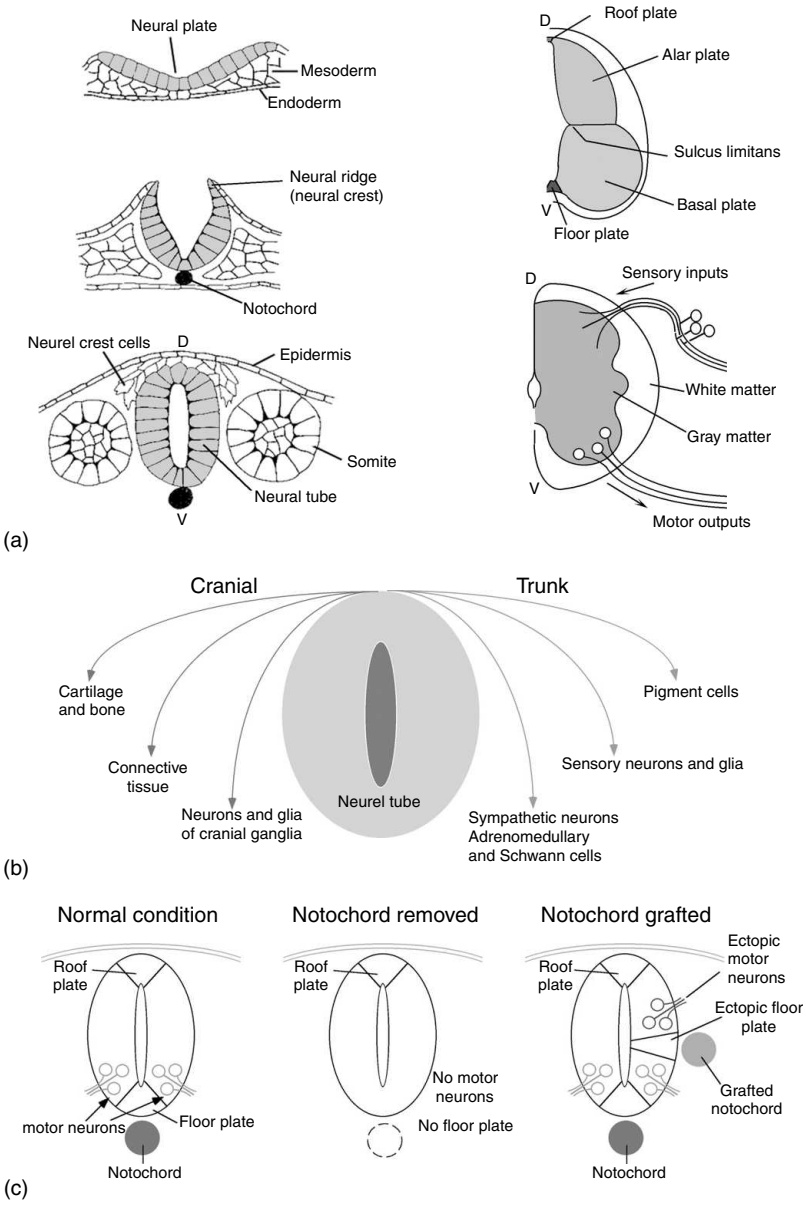

Fig. 3 Neurulation and D–V patterning of the neural tube. (a) Neurulation and D–V patterning of the neural tube during vertebrate development. D, dorsal; V, ventral. Note that cranial neural crest cells are different from trunk neural crest cells in generating a distinct set of cell types *in vivo*. (c) The role of the notochord in the neural tube D–V patterning.

tube (Fig. 3a). During the morphogenetic processes to form the neural tube, termed *neurulation*, a group of cells delaminates from the neural ridge/dorsal midline (*neural crest*) of the neural tube and migrates to generate the *neural crest cells*. These cells differentiate into components of the peripheral nervous system (PNS) as well as other types of cells including bones (Fig. 3b). The neural crest cells can produce such a variety of cell types that they have often been designated as the fourth germ layer. The timing of neural crest cell emigration varies among species. For example, mammalian cranial neural crest cells emigrate before the neural tube is closed, while chicken neural crest cells first migrate just after the neural tube closure. The neurulation step also varies from species to species. For instance, in fish embryo, neuroectoderm (the neural keel) first segregates out from the ectoderm layer as a group of cells, and later a cavity is generated in the middle of the segregated tissue to form the neural tube. Another unique process, observed in the posterior part of mouse and chicken embryos, is termed *secondary neurulation*. In this process, neural tissues are segregated from a mixture of cells in the tail bud and this forms the remainder of the neural structures in the spinal cord. The dorsalmost cells in the neural tube differentiate to constitute the *roof plate*, while the ventralmost cells form the *floor plate* with distinct features and functions (Fig. 3a). The *sulcus limitans* is an anatomically distinguishable boundary between the dorsal and ventral neural tube, and the dorsal half of the neural tube subdivided by this landmark is termed the *alar plate*, while the ventral half is called the *basal plate* (Fig. 3a). In the mature spinal cord, sensory inputs from the peripherals (i.e. dorsal root ganglia) innervate the interneurons in the alar plate (Fig. 3a). Then, the outputs from interneurons either innervate the brain or directly rule the motor neurons in the basal plate, generating the motor outputs to the peripherals (i.e. muscles) (Fig. 3a). This organization along the D–V axis in the spinal cord is also represented in the rest of the CNS.

D–V differences in the neural tube are patterned by the surrounding tissues, among which the notochord and epidermal ectoderm (i.e. surface ectoderm) seem to play pivotal roles. For example, if the notochord is eliminated at early developmental stages, no ventral identities are known to emerge (Fig. 3c). Furthermore, if the notochord is grafted into the medial region of the early chicken spinal cord, it has been demonstrated that components in the basal plate, such as the floor plate and motor neurons, are ectopically induced (Fig. 3c). The floor plate has also been shown to have inducing activity, and a component of the signaling molecules is the secreted molecule Sonic hedgehog (Shh). Both the notochord and floor plate cells express this molecule during early neural development, and experimental data support a working hypothesis whereby several types of motor neurons as well as interneurons are produced in response to the Shh gradient along the D–V axis. According to the hypothesis, the cells exposed to the highest dose of Shh become the floor plate cells, while those exposed to lower doses constitute the distinct progenitor domains in the ventricular zone. A gradient of Shh signaling is also important to eventually generate several types of motor neurons and interneurons defined by a differential expression of transcription factors and functions (Fig. 4a, b). *In vitro* experiments have indeed confirmed that different concentrations of Shh set strict thresholds to

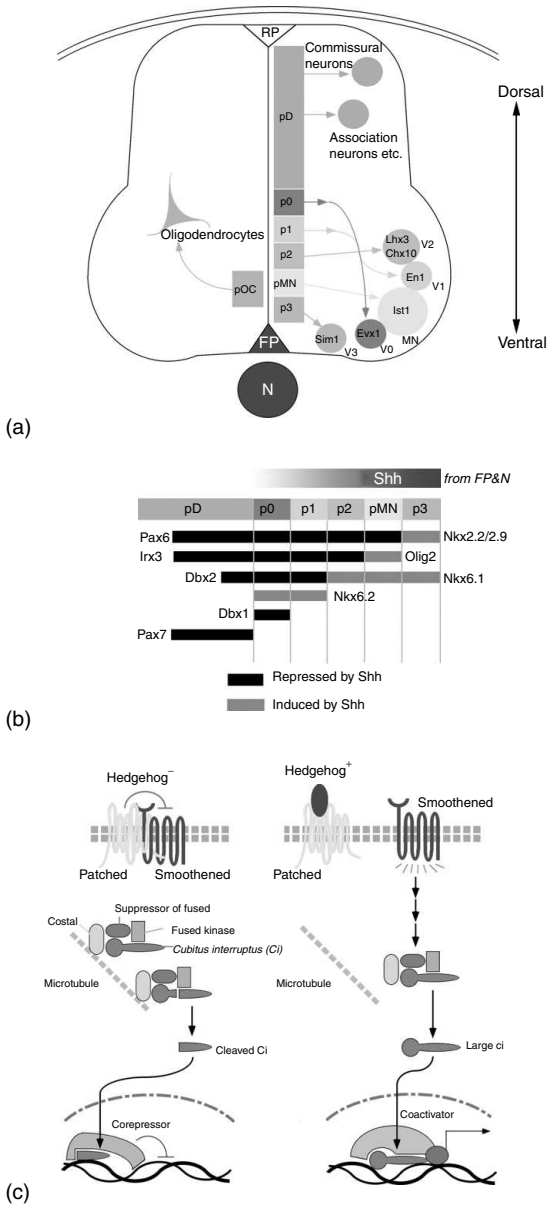

Fig. 4 Shh dependent D–V patterning in the neural tube. (a) Various cell types are generated along the D–V axis of the neural tube. The floor plate cells (FP) and the underlying axial mesoderm, notochord cells (N) produce the secreted molecule sonic hedgehog (Shh). MN, motor neurons; p, progenitor domains; RP, roof plate, (b) Ventral sources of Shh (FP and N) set a Shh gradient, inducing and/or repressing distinct sets of transcription factors within the progenitor domains. This helps generate various types of neurons defined by the functions and gene expression profiles. (c) The hedgehog signaling machinery revealed in *Drosophila*. In vertebrates, there are three hedgehogs (Sonic, Indian, and Desert), and Gli transcription factors are the vertebrate homologs of Ci (*cubitus interruptus*).

induce each cell type in the spinal cord. This raises the question of how a single molecular gradient can serve to define distinct progenitor domains along the D–V axis. The known Shh receptor components are the seven-transmembrane proteins, Patched and Smoothened, and interactions between the ligand Shh and the receptor molecules are shown to finally activate the Gli transcription factors in vertebrates (refer Fig. 4c). As the degree of receptor activation appears to control the

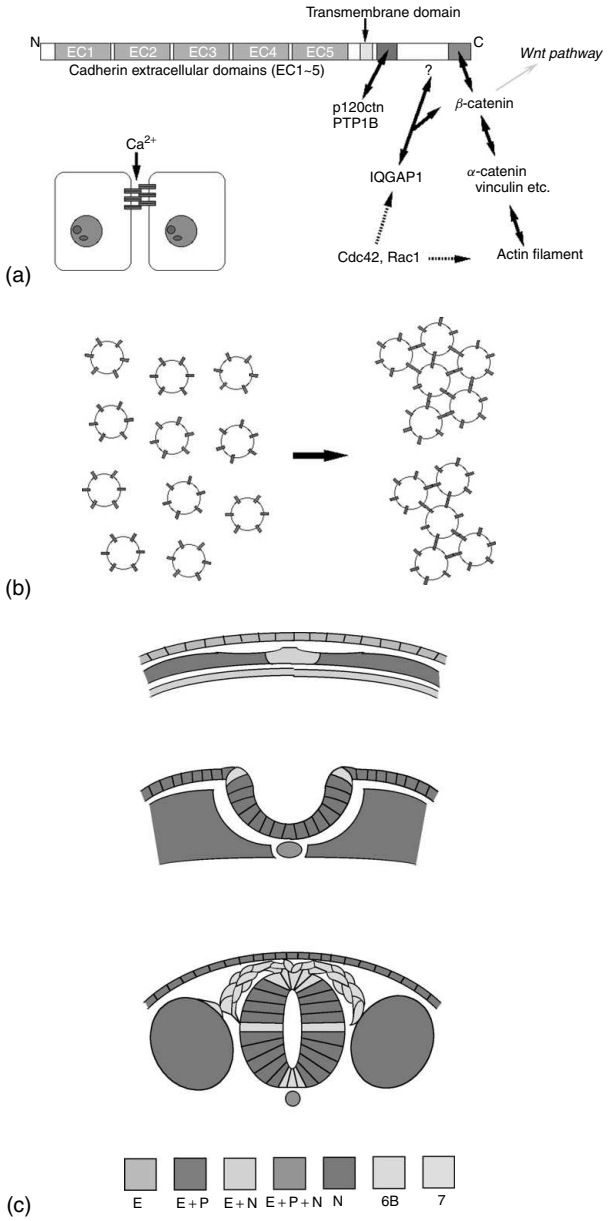
degree of Gli activation, it is assumed that such differential concentrations of the Gli molecule in cell nuclei affect the binding possibility of the target genes, allowing the distinct sets of downstream transcription factors to be switched on/off.

In the dorsal half of the spinal cord, distinct neuronal cell types are generated at characteristic times and positions. The identity and pattern of generation of these dorsal neurons are shown to be dependent initially on BMP-mediated signals that derive from the epidermal ectoderm and induce the dorsal midline cells called the *roof plate*. Roof plate cells are further revealed to provide a secondary source of TGF (transforming growth factor) beta-related signals that are required for the generation of distinct classes of dorsal interneurons. Additionally, WNT-secreted molecules are suggested to play a crucial role in constituting the dorsal cell types. For instance, when the *wnt* genes expressed at the dorsal midline of the neural tube (Wnt1 and Wnt3a) are eliminated by gene targeting in the mouse embryo, expansion of the neural crest as well as dorsal CNS progenitors is abolished. This indicates that local WNT signaling is important for the patterning and generation of various types of cells in the dorsal neural tube. Furthermore, neural crest induction has been shown to involve interactions between the neural plate (neuroectoderm) and epidermal (surface) ectoderm: If an isolated neuroectoderm and neural plate are combined *in vitro*, neural crest cells are induced at the interface between these tissues. Recently, Wnt6 localized in the early chicken surface ectoderm has been demonstrated to play a role in initiating neural crest induction, yet the detailed molecular machinery including the relationship between Wnt6 and BMP signaling has not been determined.

The alar/basal boundary, which coincides with the morphologically identifiable sulcus limitans, has been proposed to play a critical role in maintaining the D–V pattern in the neural plate/tube during development. Cadherin cell adhesion molecules could be responsible for the process, because one of the cadherin subclasses, F-cadherin, is found to delineate the alar/basal boundary cells, whereas other subclasses of cadherins demarcate a distinct cellular population in the frog neural plate/tube. Cadherin is a transmembrane protein and is known to confer rigid adhesiveness to cells in a Ca^{2+} dependent manner (Fig. 5a). More than 20 subclasses have been cloned thus far, and notable is the fact that each subclass has a

Fig. 5 Roles of cadherin cell adhesion molecules in embryogenesis (a) Cadherin is a transmembrane protein that confers rigid adhesiveness to cells in a Ca^{2+} dependent manner. Several molecules are known to interact with cadherin at the cytoplasmic domain, and they are important to tether cadherins to the actin cytoskeltons. Cadherins might be involved in the Wnt signaling pathway, as beta-catenin required for cadherin-mediated cell adhesion, is also a crucial element of Wnt signaling (Fig. 2b). (b) Cells with a particular subclass of cadherin can only adhere to cells with the same subclass of cadherin: when cells with different cadherin subclasses (red or blue) are mixed, they sort out from each other in *in vitro* aggregation assays, although some pairs of cadherins show heterotypic bindings. (c) During chicken neurulation, the expression pattern of cadherins is dynamically regulated. Note that the changes of the cadherin expression patterns are tightly linked to morphogenetic events, and it has been shown that overexpression of cadherins perturbs the processes of neurulation as well as neural crest emigrations. (See color plate p. xxiv).

specific binding property: cells with a particular subclass of cadherin can generally adhere to those with the same subclass of cadherin, although some pairs of cadherins show heterotypic bindings. Owing to this characteristic, if cells with different cadherin subclasses are mixed, they sort out from each other in *in vitro* aggregation assays (Fig. 5b). The restricted expression pattern of F-cadherin at the *sulcus limitans*



may therefore be required to prevent the intermingling of cells between the alar and basal plates. Overexpression of F-cadherin in the frog neural tube indeed resulted in the abnormal intermixing of cells in the neural tube. Chicken cadherin-7, most homologous to frog F-cadherin, further delineates the sulcus limitans, suggesting a conserved role for cadherins in maintaining this important boundary between the alar and basal plates during evolution (Fig. 5c).

Curiously, in the process of neurulation, the expression of cadherin subclasses is dynamically regulated. In chicken embryos, for instance, the neuroectoderm loses E-cadherin expression and begins to express N-cadherin (Fig. 5c). Cells at the neural ridge then lose N-cadherin expression and begin to express cadherin-6B, while the emigrating neural crest cells switch off cadherin-6B expression and acquire cadherin-7 expression (Fig. 5c). These serial switches of cadherin subclasses during development are crucial, as ectopic expression of N-cadherin in the frog embryo causes abnormal segregation between the ectoderm and neural tube. Overexpression of N-cadherin or cadherin-7 in the chicken neural tube is further revealed to result in the deterioration of neural crest cell emigration, indicating that the spatiotemporal expression pattern of cadherin is important for normal development. The repressive transcription factor, Slug/Snail, is known to be involved in epithelial–mesenchymal transition processes by downregulating E-cadherin expressions *in vitro*. This type of regulation might control emigrations of neural crest cells *in vivo*, as Slug/Snail expression delineates the neural fold during neural crest emigrations. Yet, cadherin genes are huge (~200 kbp) with large introns, and the transcriptional machineries required for the spatiotemporary restricted expression of cadherins has been poorly investigated.

2.2 A–P Patterning in the Neural Plate/Tube

It is known that tissues surrounding the future neuroectoderm at the gastrulation stage help establish A–P patterning in neural tissue. As I already mentioned earlier, Nieuwkoop proposed a two-step model in which an early activating signal has a role in inducing neural tissue with an anterior character (i.e. forebrain). Subsequently, a second posteriorizing or transforming signal converts some of the posterior neural tissues into an even more posterior character (i.e. hindbrain and spinal cord). Supporting this model, distinct tissues have been shown to induce different axial characters. For instance, in mice, it has been demonstrated that the combined action of the AVE and the node-derived axial mesoderm (prechordal plate) was important to represent anterior neural characters (Fig. 1c). Various signaling molecules required to establish the anterior character have indeed been identified. For example, secreted molecules such as Noggin and Chordin have been shown to induce anterior characters as the gene targeting mice have severe defects only in the anterior structures. Another secreted molecule, Cripto with a cysteine rich and EGF-like motif has further been shown to be a crucial morphogen organizing the mouse A–P axis (refer to Fig. 1c and the legend). Regarding the posteriorizing signals, retinoids, Wnt, and FGF signaling have been implicated as the candidates. For instance, explants from the frog anterior neural plate were shown to acquire the posterior identity when treated with FGF. Additional mechanisms must be involved in the posteriorization, as a simple block of

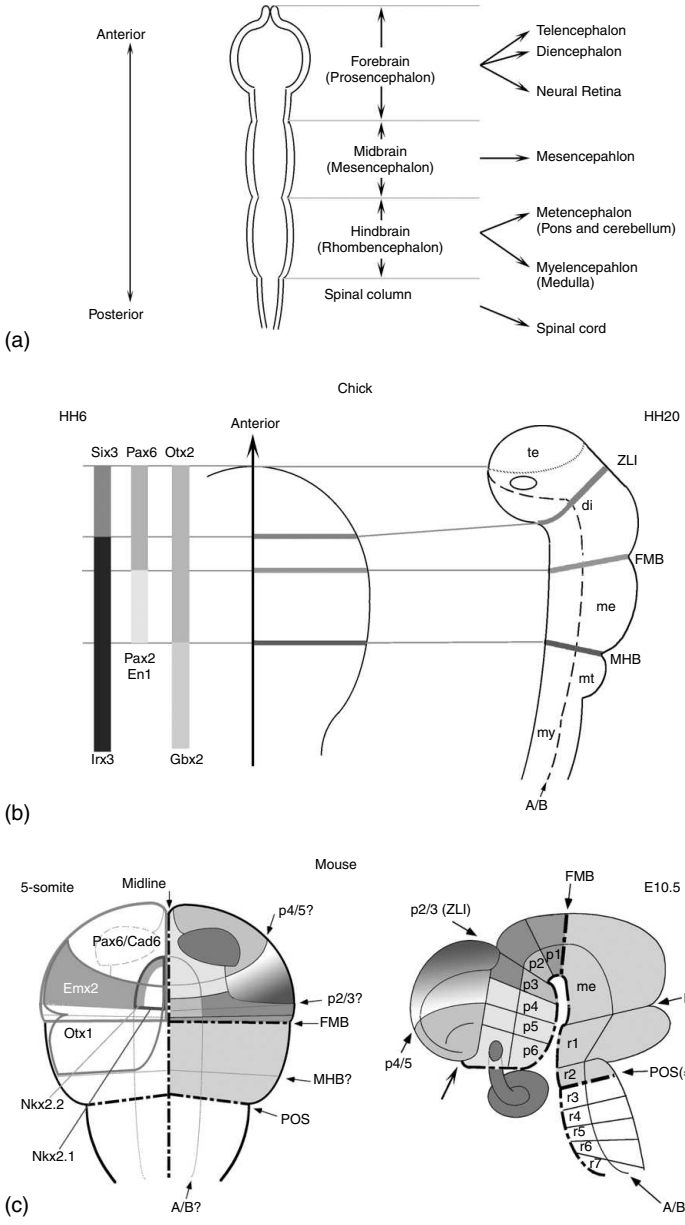
FGF was not enough to abolish the posterior patterning. Interactions among those secreted molecules could generate the regional differences of signaling events in the downstream, eventually turning on differential sets of transcription factors to represent the morphological and functional variations along the A–P axis in the neural plate/tube.

Following the neural induction and/or neurulation events, several bulges and sulci become apparent in an orderly manner in the anterior part of the neural plate/tube, generating the anatomically distinguishable segmented structures along the A–P axis. This step is termed *segmentation* and Fig. 6(a) shows how the vertebrate anterior neural plate/tube can be subdivided into major brain regions such as the *forebrain, midbrain,* and *hindbrain,* all of which have separable characteristics compared with the posterior CNS region, namely, the *spinal cord*. Within these major brain regions, further bulges and *sulci* are generated, and these minimal brain units, anatomically distinguishable during development, are defined as *neuromeres* (Fig. 6c, 7c). Curiously, some of the neuromeres, which constitute the cell lineage restricted compartment units, are considered to play a major role in maintaining embryonic brain organization, because the boundaries prevent cells, once patterned, from random intermingling during development. Neuromeres may further provide a basic framework for complex neuronal circuits since the neuromere boundaries often coincide with the territories between functional brain subdivisions and with initial axonal tracts in the embryonic brain. Next, I summarize genetic mechanisms involved in A–P patterning within the (1) hindbrain (rhombencephalon), (2) midbrain (mesencephalon), and (3) forebrain (prosencephalon).

2.2.1 Hindbrain Specification

The hindbrain region later generates the pons, cerebellum, and medulla. While the cerebellum is thought to play a central role in the coordination of complex movements, the medulla is considered as the critical center for involuntary activities such as respiration. The pons is also an important turning point for various nerve tracts. In the developing vertebrate hindbrain, seven to eight segmental units are morphologically recognizable. These units are called *rhombomeres* and play a crucial role in hindbrain patterning. For instance, distinct types of cranial motor neurons are differentiated at later stages along rhombomere organization (Fig. 7c). The neural crest migration pattern is also determined by this segmental organization, eventually affecting the metameric craniofacial structures represented in the branchial arches (Fig. 7c). What molecular mechanisms then regulate hindbrain segmentation?

The Hox transcription factors are one of the gene families that play a central role in hindbrain segmentation. *Hox* genes are originally identified as homologs of the genes involved in the segmentation of *Drosophila* embryos: The A–P axis of *Drosophila* embryos is first realized as opposing maternal mRNA gradients along the A–P axis of the egg, which are translated into transcription factors immediately after fertilization (Fig. 7a). In response to the combinatorial concentration of these transcription factors, differential sets of genes termed gap genes are then turned on along the A–P axis (Fig. 7a). Downstream of these gap gene transcription factors, pair-rule genes are activated (Fig. 7a), and finally, the segment polarity genes and the homeotic selector genes are respectively expressed to determine the polarity and identity of



each segmental unit (Fig. 7a). Interestingly, the homeotic selector genes, containing a unique DNA-binding motif with 60 amino acids called "*homeodomain*," make a cluster in *Drosophila* chromosome 3 such that their arrangement is colinear to the expression domain along the A–P axis of the organism (Fig. 7b). Lewis proposed a model in which the combinatorial expression of this class of genes

plays an essential role in conferring regional identities. Supporting the model, many anterior homeotic transformations are found in *Drosophila* embryos lacking these homeodomain-containing genes.

Intriguing is the fact that clusters similar to the *Drosophila* homeodomain-containing gene complex (*antenapedia*/bithorax complex) are found in the genome of various animals including humans, and they are named *Hox* gene clusters as the genome sequences encoding the homeodomain are called *homeobox* (Fig. 7b). Notably, the anterior boundaries of *Hox* gene expressions coincide with the rhombomere boundaries, implicating them in the important role of hindbrain segmentation (Fig. 7c). The functional analyses by gene targeting in mice (see Sect. 7 for this methodology) indeed indicate that regional identities in the hindbrain are controlled by the differential expression of these *Hox* genes along the A–P axis with gene knockout phenotypes just being similar to the *Drosophila* homeotic mutant phenotypes.

Hox genes have been revealed to be regulated by early posteriorizing signals such as Wnt, FGF, and retinoic acid (RA), all of which are secreted by surrounding tissues including somites, highlighting the pivotal role of *Hox* genes in linking the molecular events that occur between neural induction and hindbrain segmentation. For example, Krumlauf and colleagues have found several RA responsible elements in the *Hox* gene regulatory regions, where RA and its receptor complex can directly interact to control the *Hox* expression, and RA treatment has been shown to affect the Hox expression *in vivo*. Itasaki et al. have further shown that anteriorly grafted somites have an activity that shifts the expression boundary of Hox anteriorly. This posteriorizing activity of the somites can be separated with a simple treatment by RA, indicating that several factors could cooperatively regulate the Hox gene expression in the hindbrain.

One of the critical events that occur during hindbrain segmentation is compartmentalization. If a cell is labeled by vital dyes (DiI) and traced for a few days, sibling cell migration and/or proliferation is restricted within each rhombomere

Fig. 6 A–P patterning of the neural tube/plate. (a) Anterior part of the neural/plate becomes segmented during development, generating brain regions with distinct structure and functions, (b) Early patterning of the chicken neural plate by the differential expression of transcription factors. Gene expression boundaries eventually form the anatomically distinguishable territories in the brain. (a)

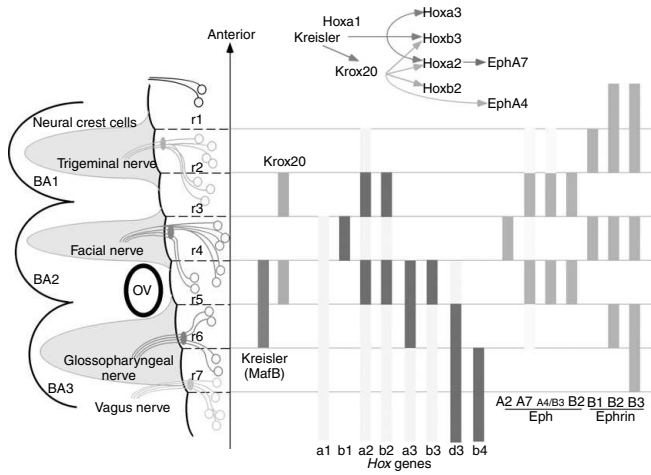
(b)



(c)

unit in the chicken embryo. Then, what molecular machinery is involved in the hindbrain compartmentalization? First of all, differential affinities among compartmental units have been suggested. The expression of several transcription factors such as *Hox* genes, Krox20, and Krisler/MafB are known to delineate rhombomere units (Fig. 7c). Downstream of these transcription factors, several cell

surface molecules are implicated in restricting cell intermingling, as dissociated cells from even-numbered rhombomeres and those from odd-numbered rhombomeres segregate from each other if mixed in suspensions. Eph receptor tyrosine kinases and their ligands, ephrins, are good candidates in conferring such differential affinity to cells: Even-numbered rhombomeres express ephrins, while odd-numbered rhombomeres express Ephs (Fig. 7c). This complementary pattern of Eph/ephrin expression is important because bidirectional signaling between cells with receptors and those with ligands leads to mutual repulsion at the interface. As a result, cell intermixing between rhombomeres is strictly regulated and rhombomere boundaries are maintained.

The cadherin cell adhesion molecules are another set of candidates involved in cell lineage restrictions between rhombomeres. As I mentioned in Sect. 2.1, cadherins confer subclass specific adhesiveness to cells. Within the mouse hindbrain, cadherin-6 is transiently expressed in rhombomere-6 under regulation of the transcription factor Hoxa-1. Additionally, R-cadherin expression has been reported in odd-numbered rhombomeres. The sorting activity between cells from even-numbered rhombomeres and those from odd-numbered rhombomeres has been shown to be Ca^{2+} dependent. Cadherins might thus serve a role in restricting cell movement during mouse hindbrain development. Cadherins are linked to the actin filaments via catenins and this provides rigid forces for cells to bind each other with polarity (Fig. 5a). Eph-ephrin signaling activates Rho GTPases and could collapse actin cytoskeletal elements to alter cell movements. Cadherins and eph-ephrin signaling may therefore act cooperatively to regulate the status of actin cytoskeltons at the rhombomere boundary region.

2.2.2 Midbrain Specification

Although no segmental organization has been identified along the A–P axis in the midbrain during development, this region contains many types of neurons with critical functions. For example, the ventral compartment produces dopaminergic neurons of the substantia nigra to control the motor functions, while the tectum (or the superior colliculus) region forms the precise positioning of neurons along the A–P axis to process visual information. Because no *Hox* genes are expressed in the brain anterior to rhombomere2, additional mechanisms are required to pattern this region.

At the early neural plate stages of chicken embryos, the expression borders of several transcription factors are known to demarcate the future midbrain territory. For instance, the anterior limit of the future midbrain (forebrain/midbrain boundary) has been shown to correspond to the

Fig. 7 A–P patterning of the developing hindbrain. (a) The genetic cascades involved in *Drosophila* A–P patterning, (b) Genomic organization and expression profiles of mouse *Hox* gene clusters are reminiscent of those of *Drosophila* homeotic genes in *antenapedia* and the bithorax complex, (c) The metameric units in the hindbrain (r, rhombomeres) delineated by the differential expression of transcription factors and Eph/ephrins are important to produce distinct sets of neurons along the A–P axis. Dark and light shading represent high and low levels of gene expression in individual rhombomeres respectively. Note that the migration pattern of neural crest cells as well as the formation of the branchial arches (BA) are also affected by the hindbrain organization.

posterior expression border of transcription factor Pax6 (Fig. 6b). The anterior expression border of another paired domain containing transcription factor Pax2 as well as a homeodomain-containing transcription factor Engrailed1 (En1) complementarily delineates the Pax6 negative domain in the neural plate (Fig. 6b). It has also been reported that the posterior expression border of the Otx2 transcription factor as well as the anterior border of Gbx2 coincides with the posterior limit of the future midbrain (Fig. 6b). Repressive interactions among such transcription factors have been suggested as being required for the establishment and maintenance of the mutually exclusive expression of these transcription factors at the future forebrain/midbrain boundary (FMB) and midbrain/hindbrain boundary (MHB). Ectopic Gbx2 expression in the midbrain using the *in vivo* electroporation (EP) method (see Sect. 7), for instance, downregulates Otx expression only within the cells expressing ectopic Gbx2. While the FMB is a compartment boundary at the mouse neural plate stages, the midbrain and hindbrain cells are able to freely intermix. Hence, the mutually repressive interactions between Otx2 and Gbx2 are very important to precisely define the MHB during early development.

The Otx2/Gbx2 expression border then generates the anatomically identifiable boundary between the midbrain and hindbrain called the *isthmus*, which harbors the local organizing activity for midbrain A–P patterning. For instance, if this region is grafted into the forebrain region, the entire structure of the posterior midbrain would be induced with its mirror image in the anterior midbrain and the topological innervations of the retinal neurons would be bifurcated (Fig. 8a). Wnt1 and Fgf8 secreted proteins appear to be the candidate signals for midbrain patterning. Wnt1 mutant mice lack the midbrain, and Fgf8 expressing cells or beads can mimic organizer activity (Fig. 8a). In addition, Wnt1 and Fgf8 signaling pathways form a regulatory loop that controls homeobox-containing transcription factors, such as En1/2, to establish and maintain the MHB organizer as well as the entire midbrain structure (Fig. 8a).

2.2.3 Forebrain Specification

The forebrain (prosencephalon), which is the most anterior portion of the CNS, gives rise to a variety of tissues during development including the eyes, telencephalon, and diencephalon. Within this area, mammals have acquired a six-layered architecture of cells named the neocortex, and the region has evolved, especially in human beings, for total cognitive association as well as linguistic communication. In the developing forebrain, segmental structures specifically termed *prosomeres* are known to appear (Fig. 6c). In chicken and mouse embryos, at least six units (p1–p6) are anatomically recognizable, and using the dye-labeling method, some of their boundaries have been shown to stand as limits of cell lineage restrictions just like the rhombomeres in the hindbrain. Several axon tracts seem to coincide with the prosomere boundaries, suggesting that prosomeres might also provide the basic framework for forebrain structures. Then, how are such prosomeres formed and maintained during development?

In the early chicken neural plate stage, mutual repression between the transcription factors, Irx3 and Six3, was found to first set a boundary within the future forebrain, which later coincided with the p2/3 boundary specifically called the *zona limitans interthalamica* (ZLI) (Fig. 6b). A recent study using the organ culture system has

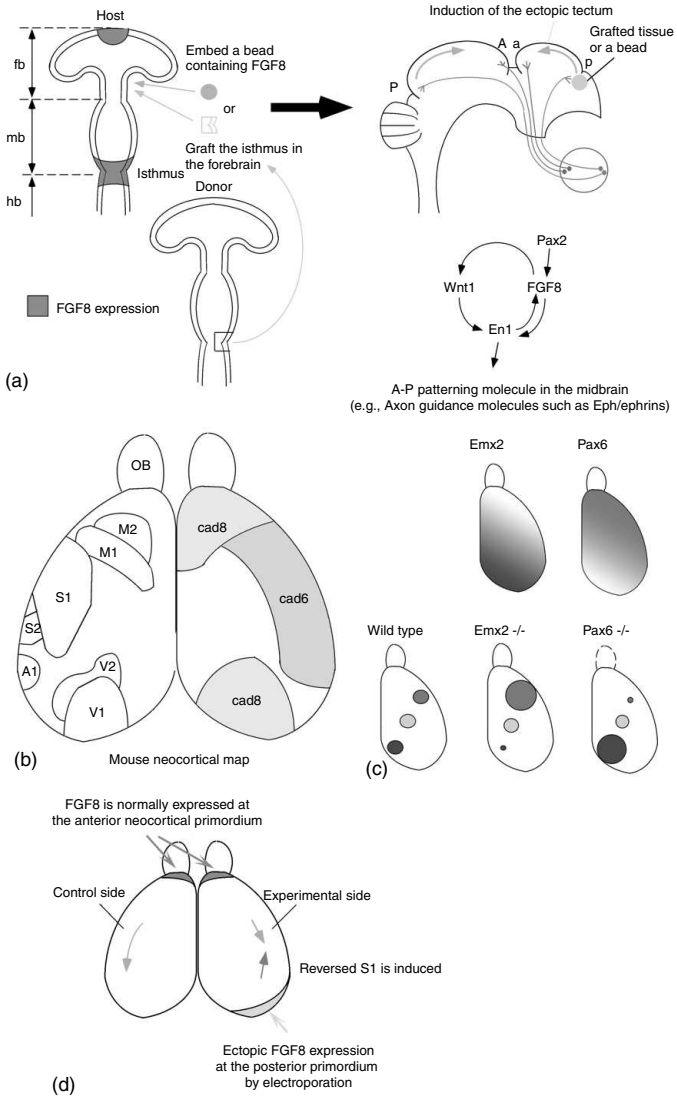


Fig. 8 A–P patterning of the midbrain and mammalian neocortex
(a) The role of the isthmic organizer in midbrain patterning. Fgf8 is a component of the organizer. See details in the text. fb, forebrain; hb, hindbrain; mb, midbrain, (b) Dorsal view of the mouse postnatal neocortex. The mouse neocortex can be subdivided into several functional areas, which are delineated by differential expression of type II cadherins. A, auditory cortex; cad, cadherin; M, motor cortex; OB, olfactory bulb; S, somatosensory cortex; V, visual cortex,
(c) Countergradient of Pax6 and Emx2 in the neocortical primordium is important to bring out differences among neocortical areas later in the development, (d) Fgf8 expressed at the anterior neocortical primordium is a crucial organizer to pattern the mouse neocortical areas.

shown that the mouse neural plate at the 2- to 3-somite stage already possesses different competencies for gene expression between the anterior and posterior regions adjoining the Six3/Irx3 gene expression boundary. This could depend partly on the fact that the underlying axial mesoderm is subdivided into the prechordal plate and notochord just beneath the future ZLI at this stage. In mouse embryos, it had been difficult to confirm if similar units exist because the embryonic development proceeds *in utero*. I performed a cell labeling experiment at the early neural plate stages using the whole embryo culture system that allows recapitulating the development *in vitro*. According to the results, there are cell populations around the 3-somite stage destined to be only forebrain cells, and the posterior limit of such cells appears to fall on the future ZLI. At the ZLI, in later developmental stages, signaling molecules such as Shh are expressed, implicating them in an organizing role in patterning the prosomeres.

Immediately after the differential competency between the region anterior to the future ZLI and that posterior to the future ZLI, the FMB is set as the Pax6 gene expression boundary, which can also be defined as a compartment boundary at the mouse 5-somite stage (Fig. 6c). In the chicken system, the FMB is revealed to be molecularly established by the 11-somite stage as the result of the mutually repulsive interactions between Pax6 and Pax2/En1 (Fig. 6b).

It is still unclear when and how the other prosomere boundaries are established during early development. In the later stages of mouse development, however, the boundary between the future cerebral cortex (ctx) and lateral ganglionic eminence (lge) has been shown to be a compartment boundary by E10.5. This boundary is called the *zona limitans intertelencephalica* and thought to correspond to the p4/5 limit. According to the fate-mapping analyses in the mouse neural plate, the future lge was indeed demonstrated to be located more anteriorly to the future ctx.

For over several decades, it has been a big problem to determine which region is the anterior most and how the floor/roof plate as well as the alar/basal boundary ends in the forebrain. This is simply because forebrain development could only be traced by morphological landmarks. However, recent gene expression analyses provide a variety of landmarks in the brain, and such molecular markers strengthen the prosomeric model. In the prosomeric model, the roof, alar, and basal plates concentrically cross the midline of the anterior most neural plate, disposing the eyes and telencephalon within the alar plate (Fig. 6b). Recent fate-mapping analyses in chicken and mouse well support the model (Fig. 6c).

Then, what molecular mechanism are involved in maintaining the prosomere organization at later stages of forebrain development? Several transcription factors are again implicated as their expression delineates later prosomeres and/or the boundaries. For example, *Pax6, Gsh2*, and *Dlx* genes demarcate restricted brain regions along the D–V axis of the mouse E12.5 telencephalon, which almost corresponds to the A–P axis of the neural plate. Interestingly, it has been demonstrated that cells from distinct regions in the telencephalon segregate from each other in a Ca^{2+} dependent manner if the cells are dissociated and mixed together. A cell surface carbohydrate epitope, CD15 (Lewis(x)), is expressed within the cortex and suggested to be the candidate molecule that mediates Ca^{2+} dependent segregation *in vivo*. In addition, several cadherins

are known to delineate prosomeres in the mouse brain, and dissociated cells have been demonstrated to sort each other out *in vitro*, dependent on the cadherin subclass expressed. In the E11.5 mouse telencephalon, cadherin-6 demarcates the lge (p5), while R-cadherin complementary delineates the ctx (p4). As the overexpression of cadherins at the ctx/lge boundary using the *in vivo* EP method (see Sect. 7 for this methodology) results in the sorting of cells with ectopic cadherin into the territory expressing the same cadherin at the boundary, this indicates that the differential expression of cadherins plays a role in maintaining the compartment boundary. Notably, R-cadherin expression in the ctx has been shown to be downstream of Pax6. Transcription factors might therefore regulate cell adhesion molecules in order to maintain their expression pattern by sorting mechanisms in the telencephalon.

Most recently, an important genetic cascade that patterns the rostro-caudal axis within the mouse cerebral cortex at later stages of development has been identified. As summarized in Fig. 8(c), the expression level of transcription factors Pax6 and Emx2 was found to make the countergradients along the mediolateral axis in the neocortex primordium at E12.5, and if one of the gradients was deprived by means of genetic mutation, regional identities were revealed to be shifted accordingly. Upstream of Pax6/Emx2 countergradients, Fgf8 expressed at the anterior neural ridge has been suggested as playing a pivotal role. Indeed, overexpression of Fgf8 in the posterior cerebral neocortex caused the duplication of the cortical area with its mirror image, indicating the organizer activity of FGF8 in the cerebral cortex primordium (Fig. 8d). As the mammalian neocortex has been thought to evolve via multiple duplication of identities, local changes in organizer activities such as ectopic sources of FGF8 expression might actually contribute to emerge the diversity of brain regions.

3 Cellular Aspects to Generate Distinct Types of Cells and/or Cellular Organization (e.g. Nuclei, Layers, and so on) in Patterned Tissue

While the neural tissue at earlier stages has just a single-cell layer organization with the epithelial character, differentiated tissues contain multiple types of cells with complex cellular organizations. There are three major classes of cells in the developing and adult CNS: *nerve, glial,* and *ependymal cells*.

Nerve cells, also called *neurons*, play a central role in constituting functional neuronal networks of the nervous system. Most nerve cells have large cell bodies called *soma*, which are accompanied by relatively large cell nuclei as well as multiple processes called either *axons* or *dendrites*: the former are defined by their ability to gather the action potentials and send electric signals to other nerve cells, and the latter are the sites for receiving these electric signals from axons. One nerve cell normally has one axon and multiple dendrites. In an *in vitro* situation, the processes of nerve cells are also called neurites, and the longest neurite has been shown to acquire axon characters. In the CNS, axon terminals of nerve cells make connections with other nerve cells and the contact sites between nerve cells are called *synapses*. Nerve cells also innervate muscles and the contact site is specifically called the *neuromuscular junction* (NMJ).

Nerve cells are considered to be all postmitotic and never generate siblings. In the process of nerve cell production, progenitor cells are known to get into the elevator movement, in which the cell body of the progenitor cells migrates from the ventricular to the marginal zone in a cell cycle dependent manner. During the movement, the asymmetrical divisions appear to produce neuroblasts and eventually generate various types of nerve cells.

Nerve cells can be distributed in different patterns in the CNS as the postmitotic nerve cells usually migrate toward their destinations after final cell division. For example, in the spinal cord, motor neurons born in the ventricular zone migrate radially and make clusters called motor columns in the ventral horn. Within the spinal motor column, neurons are further segregated into groups by means of their birthdays and targets: While the earlier generated (i.e. older) motor neurons constitute the lateral group in the column and innervate the limb muscles, the younger ones home in on the medial column and innervate the axial muscles. In the mammalian cerebral neocortex, nerve cells born in the ventricular zone travel radially as well as tangentially and settle in the mantle zone depending on their birthdays, forming the characteristic layer organization. The migration pattern of neurons born in the subventricular zone of the telencephalon is another interesting example, in which the postmitotic neurons adhere to each other to make a chain migratory pathway into the olfactory bulb. In the mature brain, neurons with distinct functions often gather and are anatomically distinguishable in the gray matter as the group of cells called the *nucleus*. At the dorsal surface of the CNS, neurons with similar functions tend to be assembled in the laminated structure called the *cortex*. The neurons with same functions may further exist in a sparse manner, and such a distribution pattern is termed the *reticular formation*, which plays a crucial role in modulating both sensory and motor inputs.

Glial cells, or simply *glia*, are supporting cells in the nervous system, and there are normally between 10 and 50 times more glial cells than neurons. Various types of glial cells with distinct functions are generated in both the CNS and PNS. For example, the oligodendrocyte attaches to the nerve axon and surrounds it to make the myelin sheath, enhancing the speed of electrical signal transmission along the axon. The Schwann cells in the PNS have a role similar to the oligodendrocyte. The astrocyte is thought to relay nutrients from blood vessels to neurons, and the microglia plays a role in maintaining and protecting the cellular organization of the CNS.

Finally, the ependymal cells are a unique population in the CNS with stem cell characteristics. They are homed in the ventricular zone and are shown to produce nerve cells as well as glial cells (astrocytes). The ependymal cells are sometimes called *radial glial cells* as they extend long radial fibers from the ventricular to the pial surface, which are thought to support the radial migration of nerve cells during development. In the adult brain, the ependymal cells continue to produce siblings and this might help generate novel neuronal circuits during the process of learning and/or memory formation. Several researchers have now begun to apply this unique character of the ependymal cells to regenerate a variety of cells, including nerve cells in the CNS.

4
Molecular Aspects of Generating Distinct Types of Cells and/or Cellular Organization (e.g. Nuclei, Layers, and so on) in Patterned Tissue

4.1
Generation of Neurons

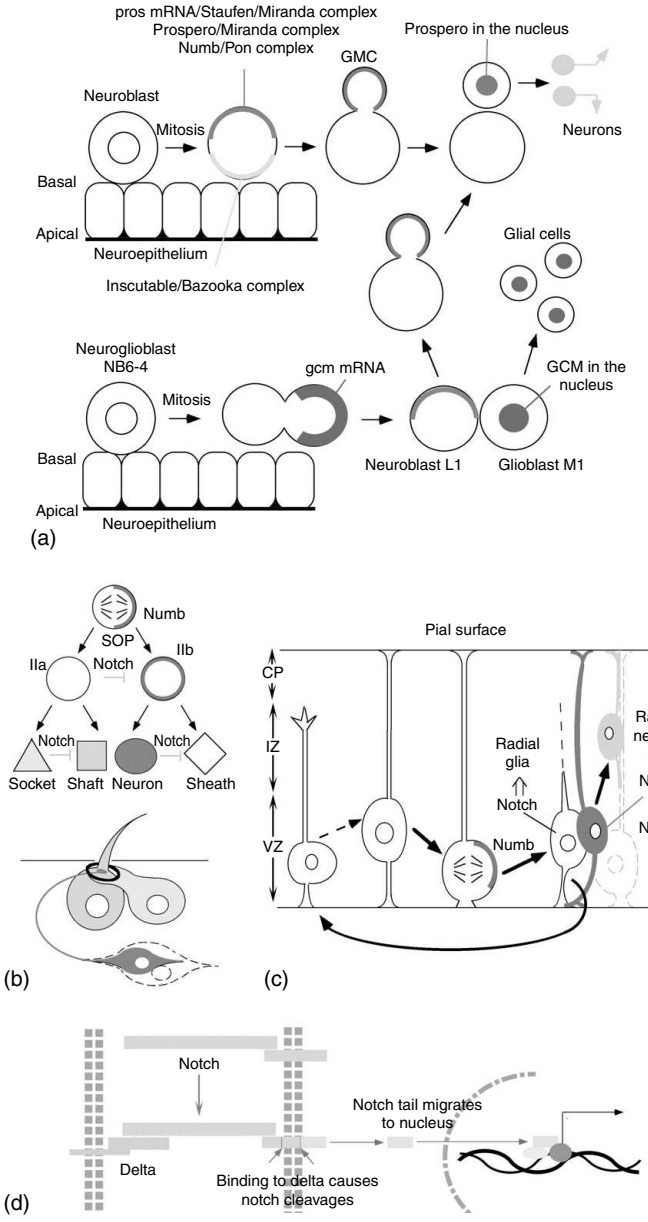
There are mainly two molecular mechanisms in generating a variety of neurons. One is the cell intrinsic mechanism (cell autonomous) and the other is the cell nonautonomous mechanism. These two mechanisms might closely correlate with each other. In the vertebrate nervous system, the latter mechanism plays major roles, yet the former mechanism is indispensable. In Sects. 4.1.1 and 4.1.2, I summarize those molecular mechanisms involved in the production of multiple cell types in the nervous system.

4.1.1 Cell Intrinsic Mechanisms

Cell intrinsic mechanisms play important roles especially in animals where cell lineage is strictly regulated during development. Cell intrinsic differences could be mainly realized by asymmetric cell divisions in which particular sets of determinants might be differentially divided into two daughter cells. For example, in the process of *Drosophila* neurogenesis, *prospero* mRNAs as well as the protein products are distributed asymmetrically in the progenitor cells (Fig. 9a). This asymmetric distribution of Prospero is crucial in producing distinct sets of neurons, because *prospero* encodes a transcription factor and the molecule is transported into the nucleus after asymmetric cell division, allowing distinct sets of genes to be switched on/off in each daughter cell (Fig. 9a). In order to localize *prospero* mRNAs as well as proteins asymmetrically in the progenitor cell, the RNA-binding protein, Staufen, and a Staufen binding protein, Miranda, which can also bind to the Prospero protein, appear to play a central role and Inscutable regulates the polarization of these proteins (Fig. 9a). Inscutable protein can also control the spindle orientation in the cell, suggesting that this protein is a main determinant of cell intrinsic differences between apical and basal compartments in a cell. Curiously, Inscutable can further interact with the Bazooka protein, another important determinant of apical–basal polarity formation in a cell. Bazooka homologs have been identified in the nematode *Caenorhabditis elegans* (Par-3) as well as in vertebrates (ASIP; atypical PKC isotype specific interacting protein), indicating a conserved mechanism for intracellular asymmetry beyond species. Notable is the fact that the *Drosophila* glial/neuronal lineage can also be initiated by the asymmetric distribution of *glial cell missing* (*gcm*) mRNA (Fig. 9a). As *gcm* encodes a transcription factor required for glial fates, the asymmetric segregation between the two daughter cells may play an essential role in the bifurcation of glioblast and neuroblast lineages (Fig. 9a).

4.1.2 Cell Nonautonomous Mechanisms

It would be very important to control the relative ratio of various cell types during neural development. In this critical process, Notch/Delta mediated cell–cell communications (cell nonautonomous machinery) appear to play a pivotal role. The Notch/Delta signaling pathway was first reported to be essential for the neurogenesis of the *Drosophila* embryo, where cells that happen to express a higher amount of ligands, Delta, inhibit lateral cells expressing receptors, Notch, to further differentiate into neurons. This process is specifically



called *lateral inhibition*. In the process of Notch signaling, the cytoplasmic region is cleaved and transported into the cell nuclei to switch on the downstream target genes (Fig. 9d). Signaling may be modified by Numb (an intrinsic determinant localized at the cytoplasmic side of cell membrane and/or Fringe (a member of glycosyltransferase). Although the initiation of this process is stochastic, a

proper number of neurons can be generated in the neuroectoderm, otherwise all cells become neurons (the so-called *neurogenic phenotype*) after neural induction. At later stages of *Drosophila* neural development, Notch/Delta signaling is utilized to control the cell type specification in the series of cell divisions. For example, after the sensory precursor cells are selected from the epithelium, each of them should produce four distinct cell types: a neuron, glia (sheath), socket, and shaft (Fig. 9b). As shown in Fig. 9(b), Notch signaling, together with Numb, seems to suppress the glia as well as shaft cells to become neuron and shaft cells. In vertebrate nervous systems, the Notch/Delta signaling pathway appears to be involved in determining primary neuron production in a regulated way; prospective primary neurons expressing the ligand Delta inhibit lateral cells expressing the receptor Notch to further differentiate into neurons, resulting in the stripe domains of neuron production along the D–V axis of the neural plate/tube. In the mammalian cerebral cortex, similar mechanisms help generate cortical granule cells (Fig. 9c). Using time lapse imaging, it has been demonstrated that a radial glial cell (ependymal cell) in the cortical ventricular zone divides to produce one neuron and a cell maintaining the radial glial cell characters (Fig. 9c). In this process, the cells that get into the neuronal lineage have been shown to inherit the Numb protein from the radial glial cells/stem cells via asymmetric cell divisions, repressing the receptor Notch activity to finally be determined as neuronal (Fig. 9c). PNS gangliogenesis is also shown to be dependent on this signaling mechanism, controlling the neuron/glia ratio in the dorsal root ganglia.

As I described earlier, early patterning events partition the vertebrate neural plate/tube along the A–P and D–V axes via a series of complex actions of secreted molecules such as BMP, Shh, WNT, FGF, RA, and so on. This directly helps in generating various sets of neurons, as a distinct address in the neural plate/tube *per se* restricts the definitive number of transcription factors able to be turned on. Besides the Shh dependent neuronal generation machinery along the D–V axis of the spinal cord, which I have already described in detail earlier (see Sect. 2.1; Fig. 4), *Hox* genes have been shown to play a role in generating distinct sets of neurons along the A–P axis. For instance, it has been demonstrated that inactivation of members of the *Hox-c* and *Hox-d* gene clusters expressed in the spinal motor neurons leads to alterations in the motor innervation of specific muscles in the limb. Additionally, in the developing

Fig. 9 Mechanisms involved in neurogenesis during development (a) Cell intrinsic machineries play crucial roles in *Drosophila* neurogenesis as well as gliogenesis. GMC, ganglion mother cell; Pon, partner of numb; pros, Prospero. (b)Roles of Numb and Notch signaling in the *Drosophila* sensory organ precursors (SOPs). (c)Neurogenesis in the mouse cerebral cortex. A radial glial cell (a stem cell) divided asymmetrically within the ventricular zone (VZ) produce a radial glial cell (Numb negative) and a radial neuron (Numb positive). The latter will migrate radially along the long process of radial glial cells, differentiate into a neuron in the intermediate zone (IZ), and finally settle within the cortical plate (CP). (d) Notch/Delta signaling machineries. Notch with 36 EGF-like repeats can bind to Delta with 9 EGF-like repeats expressed by a neighboring cell, resulting in the release of Notch cytoplasmic domain into the nucleus. The cytoplasmic tail can directly bind to DNA and transactivate target genes.

hindbrain, *Hox-a* and *Hox-b* genes have been shown to regulate the identity as well as the axonal projection pattern of cranial motor neurons. Recently, a possible role has been suggested for the secreted molecules FGFs, Gdf11, and Retinoids in regulating the *Hox-c* expression in the motor neurons along the A–P axis. It would be an intriguing subject in the near future to see how the signals that regulate A–P differences can interact with those that define the D–V axis (Shh) and/or neuron/glia ratio (Notch/Delta) to generate distinct types of neurons in a timely and spatially restricted manner.

4.2 Nuclei Formation

To arrange cells into groups after cell divisions, coordinated processes must be required. First of all, the timing of cell division has a role in sorting the final localization of neurons. For example, in the spinal cord, motor neurons generated at earlier stages are shown to occupy the distal domain. Recently, Jessell and colleagues have reported that cadherin cell adhesion molecules demarcate distinct populations of neurons in the chicken spinal motor column. Using the *in vivo* EP technique (see Sect. 7), they showed that neurons with the ectopic cadherin subclass could localize in the subdivisions of the motor column (pools) expressing the ectopic cadherin, implicating the cadherins in the important role of sorting different subclass of neurons into a pool within the spinal motor column during development.

In the thalamus, there are many distinct subdivisions in the neurons, which innervate specific telencephalic region. For example, neurons in the medial geniculate nucleus send axons to just the auditory cortex, while those in the lateral geniculate nucleus innervate only the visual cortex. As is the case with the spinal motor neurons, neurons produced at earlier stages usually settle in the lateral subdivisions within a thalamic nucleus. Recently, various types of molecular markers such as transcription factors (LIM homeodomain transcription factors, Gbx2, Dlx1, Nkx2.2, Pax6, and so on) and cell adhesion molecule cadherins were found to demarcate specific subdivisions. As cadherins have subclass specific cell adhesiveness, differential expression of cadherins may contribute to the segregation of specific cells into the thalamus subdivisions, just like the case with the motor column segregations in the spinal cord. Curiously, it has been reported that secreted molecules such as the Shh expressed at the ZLI might regulate the differential expression of transcription factors in the thalamus, implicating a genetic cascade in the regulation of nucleus formation, yet the detailed machineries have been poorly studied.

4.3 Layer Formation

In the mammalian cerebral neocortex there are six major layers (layers I to VI), which can be distinguished by differences in the morphology and density of the neurons, with the thickness of each layer varying from area to area. Neurons in each cortical layer are generated in the ventricular zone of the dorsal telencephalon and travel toward the cortical plate located in a remote position from their birthplace using the radial glial fibers as the migrating substrates, while some interneurons are known to be generated in the ventricular zone of the ventral telencephalon and migrate tangentially. Cortical layers are formed in an orderly manner from the

inside to the outside, being the very reverse of tree ring formation, in that, newly generated neurons stop their migration at the marginal zone so as to get over the predominated old neurons in the cortical plate. A series of mutant mice exist that have apparent phenotypes in layer formation; for example, the *reeler* mutation is known to affect the order of layers in that newly generated neurons cannot get over the old ones in the cortical layer and so stay inside the prepopulated cell layer, similar to the formation of a tree ring, and ultimately resulting in the reversed order of the cortical layers. The gene responsible for this phenotype encodes a large extracellular protein named *Reelin*, which is secreted by the Cajal–Retzius (CR) cells in the preplate. CR cells are thought to originate from the telencephalic ventricular zone and are the first to reach the cerebral marginal zone to form the preplate. The role of CR cells in layer formation is significant because the secreted Reelin protein appears to promote neuronal cell migration from the ventricular to the marginal zone in order to get over the prepopulated layer of cells. The Reelin receptor is thought to be a molecular complex. A component is the LDL receptor family, namely, the very-low-density lipoprotein receptor (VLDLR) and the apolipoprotein E receptor type 2 (ApoER2) expressed by the migrating cortical neurons. The cytoplasmic region of these receptors can interact with an adapter protein Disabled (Dab-1), and Reelin binding to the receptor complex has been shown to induce tyrosine phosphorylation of Dab-1. Double knockout mice for both receptor genes as well as Dab-1 mutant mice (*Scrambler* or *Yotari* mice) resulted in the reeler phenotype, indicating that these genes constitute the main complex to regulate the neuronal migration and form the normal cortical layer organization in a Reelin dependent manner. Importantly, alpha3beta1 integrin, expressed by migrating neurons was also demonstrated to be able to bind to Reelin and regulate the interaction between radial glial fibers and migrating neurons *in vitro* as well as *in vivo*. Gene knockout of this integrin resulted in reduction of the Dab-1 protein level, suggesting that integrin mediated cell adhesion might play a role in the radial glial fiber guided neuronal migration. The Reelin-Dab1 regulated cell migration machinery has further been shown to be required for the layer formation in other tissues including the cerebellum and hippocampus. In reeler mutant mice, for instance, the Purkinje cell layer was totally disorganized, and the cell arrangement in the dentate gyrus of the hippocampus was also perturbed, although cell type differentiation *per se* was not affected. This implicates Reelin-Dab1 regulated cell migration in the common role of layer formation during development and evolution.

5 Cellular Aspects to Wire up the Nerve Cells into Functional Circuits

Once the nervous system is patterned and unique sets of neurons are generated, they must be connected to each other to constitute functional neuronal circuits. In this process, neurons should precisely send axons into remote target positions. Although Ramon y Cajal had already suggested possible mechanisms explaining axon guidance in the early 1880s, experimental supports had been relatively poor for several decades after him. In the 1950s, Sperry rotated an eye in an adult newt by 180°, and made the eye–tectum connections regenerate. He then demonstrated that the axons

from the retinal neurons at the ectopic position could finally reach the original position, indicating that the axon pathfinding events are totally dependent on various environmental cues (*Chemoaffinity hypothesis*). Landmesser and colleagues also found that if the spinal cord at the limb level is rotated by 180° along the A–P axis in chicken embryos, the motor axons originating from the ectopic position could finally reach the normal muscle target.

To sense such various environmental cues, the tip of the axon is specialized into a structure called *growth cone* (Fig. 10a). During axon guidance, growth cones appear to contact either supporting cells or previously established nerve tracts from other neurons. Those cells harboring the activity to guide growth cones are named *guidepost/stepping-stone cells* and *pioneer neurons* respectively (Fig. 10a). Once a growth cone arrives at a target region, it stops and forms a stable junction with the target neuron, the maturated form of which is termed synapse. The neural circuits at this point are, however, premature and sometimes contain wrong connections. For instance, while only a single climbing fiber innervates each Purkinje neuron in the adult mouse cerebellum, multiple innervations were found at perinatal stages. Such wrong connections are eliminated in an activity dependent manner. In the mammalian visual cortex, inputs from the right eye compete with those from the left eye to make the ocular dominance column. In this process, inputs from both eyes have been shown to occupy the same area at the initial step of the development but eventually lose the connection to form the ocular dominance column. Elimination of inputs from one eye during the initial stages resulted in the loss of the ocular dominance column, indicating that this process was also activity dependent. Even in the adult brain, neuronal circuits are always modified over time mainly by changing the synaptic junctions in number and strength.

6 Molecular Aspects to Wire up the Nerve Cells into Functional Circuits

There are mainly two mechanisms to explain axon guidance; one is a contact dependent and the other is a contact-independent machinery. In the former, interaction between the transmembrane and/or membrane-bound receptor in the growth cone and its ligands exists on the neighboring cell membrane or extracellular matrix (ECM) and plays a major role, while secreted molecules from remote positions and their receptors on the membrane of growth cones are involved in the latter. The following are examples of these two mechanisms:

Fig. 10 Mechanisms involved in axon guidance. (a) A schematic drawing explaining how a growth cone can be guided to the target area. For details, see text, (b) The retino-tectum connection system in chicken. Visual information is precisely represented in the tectum because of the topographic connection pattern. In order to establish such a connection pattern, the graded expression of the Eph receptor in the retina and that of its ligand ephrin in the tectum appear to play an important role, (c) A commissural interneuron in the spinal cord can express different sets of molecules along the axon in response to various environmental cues. (d) Secreted molecule Slit mediated axon guidance in the *Drosophila* embryo is strictly regulated by the posttranscriptional modification of the Slit receptor Robo. 6.1 Contact-dependent (Short Range) Axon Guidance Mechanisms

In chicken embryos, the retinal ganglion cells in the eye send axons toward a midbrain region, the tectum. Noticeable is the fact that the connection pattern between the retina and the tectum is totally topographic; nasal ganglion cells send axons to the posterior tectum and the temporal ones to the anterior tectum. Furthermore, the dorsal ganglion cells send axons to the ventral tectum and the ventral ones to the dorsal tectum, enabling them to simply relay the two-dimensional information caught by an eye to the brain (Fig. 10b). To precisely establish such a connection pattern, Eph tyrosine kinase receptor, and its ligand ephrin have been shown to play a crucial role: EphA3 expression makes a gradient along the nasal–temporal axis in the retina (higher in the temporal; see Fig. 10b) while the ligand ephrinA2/5 makes a gradient along the A–P axis in the tectum (higher in the posterior; see Fig. 10b). The interactions between Eph and ephrin cause the collapse of growth cones, steering the axon into the area with less interactions between the receptor and the ligand. The same mechanism seems to be utilized in the thalamocortical projections in mice, as EphrinA2 and A5 expression make a gradient in the thalamic lateral geniculate nucleus, and EphrinA2/A5 double mutant mice have defects in this connection system. Regarding the upstream factors required to regulate the EphA3 gradient in the chicken retina along the nasal-temporal axis, transcription factors such as CBF-1/2 are known to make a similar gradient to EphA3. Ectopic expression of CBF-1/2 in the retina has been shown to perturb the topographic retina–tectum projection patterns, implicating these molecules in the important role of axon guidance. However, there is no evidence that these transcription factors directly regulate EphA3 expression and there could be additional uncharacterized mechanisms. In the tectum, FGF8 and Wnt1 expression at the MHB is known to be required to set up an expression gradient of transcription factors Engrailed1/2 along the A–P axis, controlling the gradual expression of ephrinA2 and A5 (Fig. 8a).

Other important molecules steering the growth cone in a contact-dependent manner are cell adhesion molecules. Cell adhesion molecules could further be a component to stabilize the synaptic junctions immediately after the axon guidance processes. There are three major types of cell adhesion molecules: (1) immunoglobulin (Ig) superfamily molecules, (2) integrins, and (3) cadherins. The following is a brief summary of the roles of these classes of adhesion molecules in axon guidance:

6.1.1 Ig Superfamily Molecules

Ig superfamily molecules are simply defined by containing the Ig domain folded by a disulfide link. Numbers of Ig superfamily molecules with multiple Ig domains are expressed in the CNS. The smallest Ig superfamily molecule expressed in the CNS is Thy-1, which contains just one Ig domain. Thy-1 is a major fraction of the surface protein on long axons, stabilizing the membrane to prevent neurite sprouting during the guidance process. N-CAM (Neural cell adhesion molecule) has five Ig domains and two fibronectin type III (FNIII) repeats, and its expression is found everywhere in the CNS, providing a good neural marker during development. *In vitro* assay showed that homophilic interaction between axons and cell substrates expressing N-CAM is crucial to promote axon outgrowth. Interestingly,

it is known that sugar groups could modify the N-CAM extracellular domain (polysialylated form; PSA-N-CAM). This modification lowers the binding affinity, providing repulsive cues for axon guidance. TAG-1/axonin-1 and L1 with six Ig domains show a curious expression pattern during the axon guidance process: The commissural neurons of the vertebrate spinal cord first send axons toward the floor plate and the axons cross the midline at the floor plate. After crossing the midline, the axons immediately change direction by 90° to ascend the spinal cord (Fig. 10c). While TAG-1 expression is detected during the initial axon guidance process and is downregulated after the turning, L1 expression is only switched on after the turning (Fig. 10c). This indicates that localization and/or expression of guidance molecules even along the same axon could be tightly regulated, allowing growth cones to sense various environmental cues over time and space. Interestingly, TAG-1 is known to heterotypically interact with Nr-CAM (Ng-CAM related Ig superfamily adhesion molecule), which is expressed by the floor plate cells. Such molecular interactions occurring at a restricted territory *per se* might have a role in changing the growth cone behaviors.

6.1.2 **Integrins**

Integrins are the cell surface receptors and their substrates are the ECM molecules such as laminin, fibronectin, and so on. Integrins consist of two subunits, namely, α- and β-chains. Distinct genes encode α- and β-chains, and differential combinations of α/β-chains produce various affinities to ECM ligands/substrates. In the CNS, multiple types of receptors and their substrates are expressed, and preferential interactions between integrins and molecules in the ECM are indeed shown to play essential roles in guiding neurites *in vitro*. The cytoplasmic domain of integrins is known to interact with cytoskeletal elements, such as vinculin, talin, and α-actinin, each of which is found to localize at the growth cones. Importantly, integrins have been shown to play a major role in directed cell migration by remodeling the cytoskeltons, and migration of mouse cortical neurons has been demonstrated to be dependent of integrins. Mechanisms that regulate cellular migrations would be utilized in the directed steering of axons.

6.1.3 **Cadherins**

Cadherins are transmembrane proteins that confer subclass specific adhesiveness to cells: cells that express one particular subclass can generally contact with those that express the same subclass in a Ca^{2+} dependent manner. Takeichi and colleagues first demonstrated that functional neuronal circuits in the chicken nervous system were subdivided by differential expressions of N- and R-cadherin. In the mouse thalamocortical connection system, expressions of type II cadherins have also been shown to delineate the specific division in the thalamus as well as the neocortical area. Furthermore, cadherin-6 expression was found to demarcate entire parts of the neuronal circuit such as the auditory circuit. Redies and colleagues have revealed that such differential expression patterns along the neuronal circuit play a crucial role in finally targeting the axons into a specific area by means of the EP mediated cadherin overexpression experiment. In the *Drosophila* embryo, it has also been shown that *D*N-cadherin plays a role in the segregation of axon tracts in a fascicle, otherwise the neural circuits were totally disorganized.

6.2 Contact-independent (Long-range) Axon Guidance Mechanisms

Many secreted molecules and their ligands play a central role in steering axon guidance. For example, interneurons in the vertebrate spinal cord send the commissural axons toward the ventralmost midline cells, the floor plate. Growth cones then cross the midline and project anteriorly as shown in Fig. 10(c). In the first step of these processes, *Netrin* secreted from the floor plate has been shown to have an activity that attract the growth cone expressing the receptor DCC (Deleted in Colorectal Cancer), an Ig superfamily molecule with four Ig domains and six FNIII repeats. Netrin was originally identified as the gene responsible for the uncoordinated cell migration phenotype (unc-6) in *C. elegans*, and importantly, it is known that Netrin can function as a repellant if the DCC receptor interacts with another receptor UNC-5. The trochlear motor neurons are located in the ventral region of the hindbrain and send axons dorsally. Netrin has indeed been shown to regulate this axon guidance step in a repulsive manner, yet the receptor components in this process are not confirmed to be UNC-5 dependent. Recently, the *Drosophila* Netrin receptor Frazzled (*Drosophila* DCC homolog) has been demonstrated to guide axons by controlling Netrin distribution. In this model, Netrin captured and relocated by the receptor Frazzled along the pioneer axon, could further act as a contact-dependent attractive guidance cue for growth cones expressing unknown Netrin receptors other than Frazzled, implicating complex molecular machineries involved in the Netrin-mediated axon guidance (Fig. 10a).

The secreted molecule Slit can act as a repellant and the receptor is an Ig superfamily member Roundabout (Robo) with five Ig domains and three FNIII repeats. In *Drosophila*, Slit is expressed at the ventral midline cells and this prevents axons that had once crossed the midline from recrossing it (Fig. 10d). Therefore, growth cones in the Slit receptor Robo mutants cross the midline many times (Fig. 10d). Notable is the fact that growth cones after crossing the midline become sensitive to Slit repulsive cues in the wild type, although the Robo mRNA is expressed by almost all neurons before crossing the midline (Fig. 10d). It is revealed that a transmembrane protein, Commissureless (Comm), transiently inactivates the Robo protein until growth cones cross the midline, otherwise axons can never cross the midline because of the repulsive activity of Slit, resulting in the commisureless phenotype in the mutant (Fig. 10d). As the Robo protein is found to be sequestered in the internal vesicles of growth cones before crossing the midline, Comm might regulate the localization of the Robo protein during axon guidance. Robo has further been demonstrated to be able to interact with DCC, the Netrin receptor. This interaction has been shown to be essential not only to silence the Netrin attractive signals but also to potentiate the Slit repulsive signals after crossing the midline.

Semaphorins are another type of secreted molecule, and both neuropilins and plexins are the receptor components of semaphorins. In the mouse, neuropilin-1 (NP-1) is a known receptor component of SemaphorinD (SemaD; the human homolog is named SemaphorinIII, while the chicken homolog is termed CollapsinI) and is expressed by the neurons in the

dorsal root ganglia (DRG). *In vitro* experiments have revealed that SemaD expressing cells indeed repel or collapse growth cones from DRG neurons, whereas growth cones from DRG neurons isolated from NP-1 gene targeting mice cannot be affected by SemaD expressing cells. *In vivo*, efferent axons from the NP-1 mutant DRG were found to be defasciculated and/or harbor excess spreading, suggesting an important role for NP-1/SemaD in constituting the guidance pathway. The NP-1/SemaD interactions also appear to regulate the initial patterning of projections from neocortical neurons: cortical neurons expressing NP-1 sense the SemaD signal from the marginal zone, sending efferent axons to avoid the SemaD signals.

Receiving various contact-dependent and contact-independent signals and/or cues, migrating growth cones sum up these stimulations and determine the final direction to go. Such decisions are mainly made within the cytoplasm of growth cones, and small signaling molecules play major roles. For example, VAB-8, a cytoplasmic protein with kinesin motor similarity, is normally required for the posterior axon guidance in *C. elegans*, and ectopic expression of VAB-8 has been shown to be sufficient to totally reverse the direction of axon outgrowth. The ratios of activity of a cytoplasmic tyrosine kinase, ABL, its substrate ENA, and the tyrosine phosphatases, which antagonize ENA, have also been demonstrated to be balanced by various Robo mediated guidance signals and finally set a direction to go. Activity and/or localization of a second messenger such as cyclic-AMP and cyclic-GMP have further been revealed to affect the final direction to go in *Xenopus* spinal axons and the cortical efferents respectively. Regarding the turning response of growth cones, local activation of the Rho family of GTPases, which is able to rearrange the cytoskeltal organization, has been implicated. For instance, Eph/ephrin interactions could modulate Rho activity, yet the detailed machinery that link distinct GTPases to other guidance cues is not well understood.

It should be apparent that the molecular mechanisms involved in axon guidance are used in controlling the direction of cellular migrations. For instance, the Eph-ephrin repulsive signals together with the cadherin-mediated cell adhesion machinery play a crucial role in generating cell lineage restriction between neuromeres (see above). Neural crest cells also require Eph/ephrin signaling, when they migrate from the dorsal neural tube and travel toward their final locations. Furthermore, the rostral migration stream from the ganglionic eminence to the olfactory bulb in the forebrain as well as the cytokine induced leukocytes migration has been shown to be dependent on Slit signaling. Such cellular machineries are so important that they might repeatedly be utilized during development and evolution.

6.3 Plasticity of the Neuronal Circuit-potentiation of Synaptic Transmission

Here, I just outline the molecular mechanisms involved in the potentiation of synaptic transmission, because detailed mechanisms have been well summarized in a chapter of the previous series written by Dr Eric Kandel and references therein.

As I described earlier, it has been reported that the morphological as well as physiological features of synaptic junctions can vary over time in the mature brain. For instance, if an excitory presynaptic neuron is artificially stimulated at

high frequency, the postsynaptic membrane potential is known to increase and the situation can last from minutes to several hours. This persistent increase in the synaptic membrane potential is called *posttetanic potentiation* and in the *in vivo* context, the process is called long-term facilitation (LTF) in *Aplysia*, while in vertebrates it is named long-term potentiation (LTP). Morphologically, many buds and/or branches termed *spines* are formed along the postsynaptic dendrites. In addition, the area of synaptic contact has been demonstrated to become broader during LTP. Molecularly, it is revealed in the excitory synapses that components of the postsynaptic ion channels are modified to facilitate the Ca^{2+} permeability through the postsynaptic membrane. Increased amounts of Ca^{2+} then activate the Ca^{2+} dependent kinase and further modify ion channels to increase the Ca^{2+} permeability. Continuous Ca^{2+} accumulations finally activate the PKA pathways at the postsynapse, resulting in turning on a set of gene transcriptions, such as cell adhesion molecules, to strengthen the synaptic junction. From the postsynaptic membrane, signaling molecules such as nitric oxide (NO) and neurotrophic factors, such as BDNF (brain-derived neurotrophic factor), are thought to be released and affect transmitter release as well as survival rates of the presynaptic neuron terminals. Neurotrophic factors further play an important role in modulating components of ion channels. Recently, the role of those genes that are implicated in LTP formation have been eliminated by the gene targeting method in mice (see Sect. 7), and these mice more or less showed aberrant phenotype in the activity dependent generation of brain functional units during development as well as during learning and memory processes at adult stages, indicating LTP might be a crucial element of these intricate processes of the brain.

7 How can Molecular Functions in Complex Tissues be Studied?

Many methods have been established to determine molecular functions *in vivo*. There are basically two methods to examine molecular functions: *loss-of-function* and *gain-of-function* studies. In the former, a gene and/or its protein product of interest is eliminated in the relevant tissue and/or entire organism, and researchers analyze the abnormalities to understand its normal functions. In the latter, a gene and/or its protein product is ectopically expressed in the tissue where the gene is not expressed, and researchers examine the acquired phenotypes of the tissue to know its original functions. Here, I briefly outline emerging methodologies to clarify the complex molecular functions in the brain.

7.1 Loss-of-function Studies

Applying materials that block generation of a gene product and/or the function of the gene product would be the simplest way in this criterion. For example, several drugs/antagonists are known to block functions of specific sets of ion channels expressed by neurons, and these reagents have been playing pivotal roles in elucidating synaptic functions in the nervous system. Designing *dominant negative molecules* could be another option to inhibit the normal functions of endogenous molecules. For instance, several types of receptors such as Notch, BMP receptors, FGF receptors, and so on are

known to be activated through dimer formations, and if truncated forms are expressed, normal receptor functions are effectively perturbed (Fig. 2a). In the *C. elegans* system, double-stranded RNA sequences, which are simply designed from the coding sequences of a gene of interest, have been demonstrated to specifically interfere with mRNA transcription and/or translation of the gene. This mechanism termed *RNAi* is now shown to be applicable not only to invertebrates but also to vertebrates including the mouse. Applying the *antisense oligonucelotides* for a given gene sequence, has also been revealed to block mRNA translation. Most recently, it has been demonstrated that the *morpholino oligonucleotides* serve as the best tool to stably block gene functions because the morpholino reagents are not degraded, thereby inhibiting mRNA translation for a long time.

Generating an organism that completely lacks a gene of interest is a prevailing method, and the manipulated organism could yield more reproducible and reliable results. In the mouse, embryonic stem cells (ES) that can differentiate into all cell types in an organism have been established, and it is now a routine process to replace a gene of interest with a drug selection gene in the ES cells via homologous recombination. Selected ES cells can directly be injected in a host embryo, and chimeric mice containing cells derived from the gene manipulated ES cells are easily obtained. If ES cell–derived cells contribute to the germ line, mice homozygous for the mutated locus can be finally produced by means of serial mating processes (Fig. 11). This procedure, called *gene targeting* or *gene knockout*, has greatly contributed to the understanding of the unveiled functions of genes expressed in the mouse brain. Major problems in loss-of-function studies are that redundant functions of related genes sometimes mask the mutant phenotypes and that the abnormalities at earlier developmental stages and/or lethality prevent the mutant phenotypes from being examined at later stages. The former problem might simply be overcome by generating double or more related gene knockouts, while the latter could partly be solved by using the conditional gene knockout system that allows the gene of interest to be inactivated in a spatiotemporally restricted manner.

7.2 Gain-of-function Studies

To express a gene of interest ectopically, ubiquitous promoters such as heat shock, beta actin, cytomegalovirus (CMV) promoters, and so on must be linked to the gene, and the construct should be delivered into tissues or organisms. If a tissue or cell type specific overexpression is required, the researchers could use proper types of promoters. For example, the promoter of neuron-specific enolase is widely used to drive the neuron-specific expression of exogenous genes. Synthesized mRNA with a 5′ cap can also be injected into a fertilized egg or the blastomere of a developing embryo, and strong expression from the injected mRNA has been reported in the zebrafish and frog systems. In the mouse, the constructs for overexpression can be easily microinjected into the pronuclei of fertilized eggs, and mice lines with the exogenous gene will be obtained after oviduct transfer of the injected eggs.

Recently, the EP mediated gene transfer method into living embryos and/or tissues has emerged a powerful tool. Using controlled square pulses instead of authentic pulses with exponential decay,

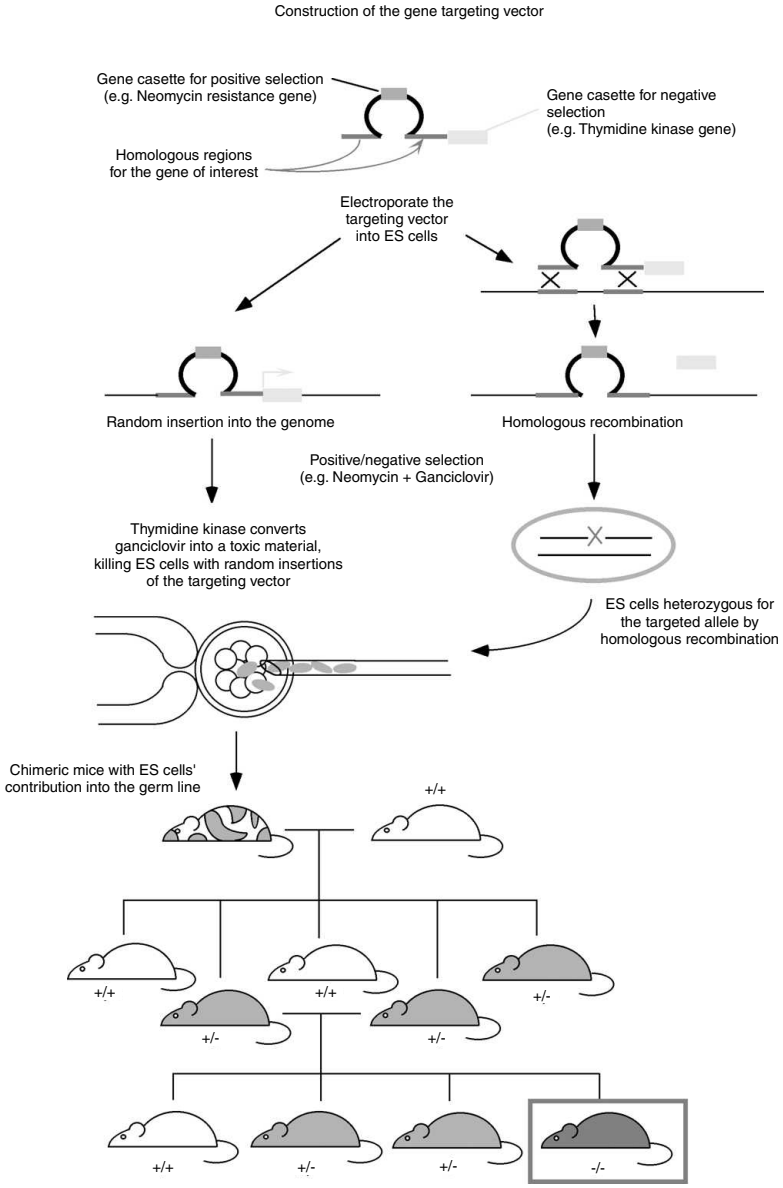

Fig. 11 How to generate gene targeting (knockout) mice.

it is now possible to drive gene expressions in any tissue at any developmental stage. Compared to the virus mediated gene transfer method, EP mediated gene transfer is less toxic to the relevant tissue as well as for researchers. Furthermore, EP is superior in its capability to control the area of gene transfer because DNA constructs with a negative charge will only migrate to the tissue facing the

positive electrode, directed by the electric field generated during EP. EP may further be combined with loss-of-function studies, as EP can target any charged molecules. Indeed, RNAi as well as morpholino oligo-mediated gene attenuation in a restricted area using EP has already been reported. Hence, EP will offer a relatively high-throughput means of assaying or evaluating gene function and regulation, which will be important in light of the flood of information coming from the genome projects.

Acknowledgments

I would like to thank Dr. Robb Krumlauf for valuable suggestions in preparing the manuscript at the Stowers Institute for Medical Research, Kansas City, MO, and an anonymous reviewer for critical reading of the manuscript. I also thank the members of the Krumlauf lab for helpful discussions. Takayoshi Inoue is supported by the Human Frontier Science Program Long-term fellowship (LT00293/2000-M).

Keywords

Calcium
The fifth most abundant element of the human body; it has a stabilizing function in shells, bones, and teeth (bound as hydroxyapatite), and in proteins in the extracellular fluid. Inside cells, calcium functions as a second messenger by interacting with specific Ca^{2+} binding proteins (e.g. calmodulin).

Calmodulin
A highly conserved, intracellular Ca^{2+} binding sensor protein involved in triggering Ca^{2+} signals. It contains four helix-loop-helix or EF-hand Ca^{2+} binding domains.

Channel
Integral membrane proteins responsible for transport across membranes; opening and closing (i.e. gating) can be voltage-, ligand-, or store-operated.

EF-hand Proteins
The term coined by R.H. Kretsinger to describe the helix-loop-helix calcium binding domains of specific proteins. The highly conserved motif (first described on the basis of

the crystal structure of parvalbumin containing six helices, A–F) in which certain amino acids are invariant consists of two helices enclosing the Ca^{2+} binding loop. As a model, the forefinger and the thumb of the right hand can resemble the two helices (e.g. E and F of the second Ca^{2+} binding domain of parvalbumin), and the bent midfinger, the enclosed loop, hence the EF-hand.

Exchanger
A transmembrane protein using the downhill gradient of one ion as an energy source to transport another ion against its gradient across the membrane (e.g. Na^{+}/Ca^{2+}).

Pump
A transmembrane protein using ATP or another nucleotide triphosphate as an energy source to transport an ion against its gradient across the membrane.

Second Messenger
Intracellular small molecules (e.g. cyclic nucleotides or inositol polyphosphates) or ions such as Ca^{2+}, indispensable for the transduction of signals converting extracellular stimuli (e.g. hormones = primary messengers) into intracellular responses.

Calcium is of pivotal importance for many biological processes. It may have a rather static, structure-stabilizing role, or it may participate as one of the second messengers of the cell in signal transduction pathways, fulfilling a more dynamic function. This is made possible by some specific properties of the Ca^{2+} ion (e.g. high dehydration rate, great flexibility in coordinating ligands, largely irregular geometry of the coordination sphere). The control of calcium homeostasis is of central importance to the organism, involving an exchange of the mineral between the skeleton (as the major calcium reservoir), the intestine, and the kidney (as the organs of calcium absorption or reuptake), from the extracellular fluid (ECF) and intracellular calcium, respectively. This highly integrated process consists of a number of hormonally controlled feedback loops and an elaborate system of channels, exchanger, and pumps to control Ca^{2+} fluxes into and out of cells. This article describes the different roles of calcium in the regulation of biological functions and the proteins involved in these processes.

1 Introduction

Calcium is one of the most common elements on earth, and it is the fifth most abundant element of the human body. Next to its central role in cellular functions as one of the second messengers, calcium is a major constituent of the skeleton. It has a stabilizing function in shells, bones, and teeth and therefore is an old component of organisms, the record

being 2×10^9 years (blue–green algae). In minerals as well as in solution, calcium occurs predominantly in a complex form, mostly as calcium phosphate (e.g. hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$]), which makes up 60% of the weight of human skeleton, that is, the skeleton of a man contains 1.0 to 1.3 kg of calcium, that of a woman 0.8 to 0.9 kg, comprising 99% of the total calcium of a human body. Compared to this amount, the calcium found in the extracellular fluid and intracellularly in the cytosol or in other intracellular compartments is almost negligible. In the ECF or in the lumen of intracellular reticular systems, the calcium concentration is millimolar (2–5 mM, of which about 50% is unbound, i.e. corresponds to free Ca^{2+} concentration), whereas the cytosolic free Ca^{2+} concentration of a resting cell is about 100 to 300 nM. This results in a steep concentration gradient of ionized Ca^{2+} across cellular membranes, which is regulated by a variety of channels, pumps, and other transporting systems controlling the fluxes of Ca^{2+} into and out of the cell and between the various intracellular compartments. On the other hand, calcium homeostasis of the ECF is maintained through a highly integrated and complex endocrine system. This involves the interplay between a receptor sensing the level of Ca^{2+} in ECF (see below) and two antagonistic polypeptide hormones, parathyroid hormone (PTH) and calcitonin (CT), and a Vitamin D metabolite, 1,25 $(OH)_2D_3$ (see Fig. 1). They measure the level of calcium in the ECF and regulate its flow into and out of the ECF by acting on target cells of the intestine, kidney, and bone. Normally, PTH prevents calcium of the ECF from falling below a threshold level, whereas CT prevents abnormal increases of serum calcium. PTH is also responsible for the formation of 1,25 $(OH)_2D_3$, which acts on specific receptors in the intestine to promote absorption of Ca^{2+}.

At the end of the nineteenth century, the English physiologist Sidney Ringer discovered that calcium plays an essential role in regulating the contraction of the heart, but for decades, calcium was considered to be a specific factor merely important for muscle contraction. Evidently, the general implication of Ringer's observation came ahead of its time. It needed the formulation of the "second messenger" concept, which was developed by Earl Sutherland on the basis of the discovery of cyclic AMP as an intracellular regulatory constituent. It was supported by the work of Ebashi et al. who showed how Ca^{2+} works in skeletal muscle, and identified troponin C as the first member of the EF-hand type calcium binding proteins. However, it was not until the discovery of calmodulin by Cheung and Kakiuchi in the sixties of the twentieth century to realize the pivotal role of Ca^{2+} as a general regulator of cellular functions. This is made possible due to the tightly controlled steep concentration gradient of ionized Ca^{2+} across cellular membranes. If a cell becomes activated because of an external signal, this often results in up to a 100-fold rise in the intracellular free Ca^{2+} concentration owing to the uptake of extracellular Ca^{2+} and/or the release of Ca^{2+} from intracellular stores. These changes in the free Ca^{2+} concentration can cause significant oscillations of Ca^{2+} in the cytosol providing the possibility of signal transduction for a number of different cellular activities (e.g. muscle contraction; glycogen metabolism; fertilization; cell growth, division, and apoptosis; excitation–contraction and stimulus-secretion coupling; mineralization). Many of these functions are accomplished through the interaction of Ca^{2+} with specific proteins, resulting in specific modulations of

protein–protein interactions owing to conformational changes of the Ca^{2+} receptors.

2 Ca^{2+} Ligation

Ca^{2+} ligation usually occurs via carboxylates (mono- or bidentate) or neutral oxygen donors since the calcium ion overwhelmingly prefers oxygen as donor groups of ligands. Owing to the great flexibility of calcium in coordination (coordination numbers usually 6–8, but up to 12 are possible) and a largely irregular geometry, both in bond length and in bond angles, calcium has a superior binding property to proteins as compared to Mg^{2+}, which requires a fixed geometry of an octahedron with six coordinating oxygen atoms and a fixed ionic bond distance due to the smaller ionic radius (0.64 Å) as compared to 0.97 Å of calcium. This difference in flexibility of complexation geometry permits calcium a greater versatility in coordinating ligands, leading to a higher exchange rate. This is reflected in a three-orders-of-magnitude difference in dehydration rate between the two ions, which makes Ca^{2+} much more suitable as a signal-transducing factor, especially in the presence of a high excess of Mg^{2+}, the concentration of which is in the mM range on both sides of the cellular membrane.

3 Calcium in the Extracellular Space

It was stated in the introduction that calcium in the ECF is tightly controlled to maintain its concentration in a range of 2 to 5 mM. One of the important functions of Ca^{2+} in the ECF is to stabilize the structure of proteins and to mediate cell–cell or cell–matrix interactions. As a consequence, there are a number of important extracellular processes that require calcium, such as blood clotting, complement activation, or interaction of cell-surface receptors with their ligands (e.g. Notch signaling). One important difference in comparing the Ca^{2+} binding sites of extracellular and intracellular proteins (e.g. EF-hand proteins, see below) is the spatial arrangement of the ligating groups. As it will be discussed in detail below, the intracellular Ca^{2+} binding proteins show a sequential arrangement of their ligating residues in contrast to the extracellular proteins in which these ligands are usually located at distant positions in the amino acid sequence (e.g. α-lactalbumin). Therefore, those proteins have a preformed cavity of Ca^{2+} binding sites with a relative high degree of rigidity with the consequence that the on-rate for Ca^{2+} binding is fairly slow. Since, on the other hand, the off-rate is relatively fast, the affinity of Ca^{2+} for the extracellular proteins is usually low. However, owing to the relative high concentration of Ca^{2+} in the ECF, these proteins occur in their Ca^{2+} bound form and are therefore protected against proteolytic cleavage.

Another important function of Ca^{2+} in the extracellular space is in mediating cell–cell adhesion. Essential for these cellular contacts are proteins called *adherins*. These transmembrane glycoproteins require calcium for their cell-binding activity. One of the best-studied molecules is uvomorulin or E-cadherin. The extracellular part of this protein is largely composed of three repeating domains, each containing two putative Ca^{2+} binding sites different from the later-described EF-hand binding

sites, but rich in aspartic acid and asparagine residues. Recently, it was shown that replacing a single aspartic acid residue by either lysine or alanine in one of these sites renders the protein more susceptible to protein degradation due to the loss of Ca^{2+} binding and abolishes the adhesive function of the molecule.

Bone-forming cells, osteoblasts, synthesize and secrete a number of noncollagenous Ca^{2+} binding proteins such as osteocalcin, osteopontin, and osteonectin that bind to bone minerals such as hydroxyapatite in a calcium-dependent manner. Osteocalcin belongs to the class of Ca^{2+} binding proteins rich in the unusual amino acid γ-carboxyl glutamic acid mediating the Ca^{2+} binding property, whereas osteopontin, a glycoprotein, is rich in sequences of aspartic or glutamic acid residues responsible for Ca^{2+} binding. In addition, both proteins contain arginine-glycine-aspartic acid sequence domains known to be important in mediating binding to cell-surface receptors. Osteonectin, on the other hand, is an extracellular Ca^{2+} binding protein that can contain at least one EF-hand type of high-affinity Ca^{2+} binding sites that are normally typical for *intra*cellular Ca^{2+} binding proteins. One interesting abnormality of this EF-hand is the fact that it is stabilized by an S–S bridge that normally does not occur in EF-hand type proteins (see below).

Similar to the intracellular Ca^{2+} binding proteins that are composed of EF-hand domains (see below), most extracellular proteins are assembled from a limited number of domain structures or modules. This is well documented for the calcium binding domains of a number of extracellular proteins like the γ-carboxyl glutamic acid–rich Gla-domain in the vitamin K–dependent clotting factors, the cadherin module, or the epidermal growth factor (EGF)-like domain. The latter is one of the best-studied examples and should be described in more detail.

3.1 The Calcium Binding EGF-domain

The epidermal growth factor or EGF-like domain is one of the most common modules identified in extracellular proteins. It plays a general role in cell–cell adhesion, blood coagulation, and receptor–ligand interaction. EGF modules contain about 40 to 45 amino acids including 6 cysteine residues that normally build S–S disulfide bond bridges. A distinct subset of EGF-domains containing a calcium binding domain (cbEGF) has been identified and its structure studied in detail. A consensus sequence associated with calcium binding has been identified as D/N-*x*-D/N-E/Q-*y*-D/N-*y*-Y/F, where *x* symbolizes a variable amino acid, *y* a variable sequence of amino acids, and D/N, E/Q, and Y/F represent the usual one-letter codes for aspartic acid/asparagine, glutamic acid/glutamine, or tyrosine/phenylalanine respectively.

CbEGF domains have been identified in a variety of proteins such as different coagulation factors, the low-density lipoprotein receptor (LDLR), the cell-surface signaling receptor Notch or the extracellular matrix protein fibrillin-1. In most of these proteins, the cbEGF domains exist as multiple tandem repeats. In a number of proteins, mutations within cbEGF domains have been linked to genetic diseases affecting blood clotting owing to factor deficiency, familial hypercholesterolaemia owing to mutations in the LDLR, inherited forms of cerebrovascular disorder such as CADASIL owing to mutations or deletions in the Notch signaling receptor, or the

Marfan syndrome owing to mutations disrupting the pair-wise interaction of cbEGF domains in fibrillin-1.

3.2 The Extracellular Calcium Sensor

As stated before, calcium in the extracellular fluid is tightly controlled because of a strict regulation by different hormones keeping the level of calcium concentration within a narrow window (see Fig. 1). Receptors of the different hormones, such as PTH, CT and Vitamin D_3, involved in this regulation have been identified, but the molecular basis for sensing the extracellular calcium level was poorly understood. On the basis of several observations, however, it was postulated that a cell-surface Ca^{2+}-sensing receptor might exist with functional similarities to the G-protein–coupled receptors of the Ca^{2+}-mobilizing hormones. In 1993, Brown et al. reported the successful cloning and characterization of a 500 kDa protein from parathyroid glands with a large, extracellular N-terminal region and a smaller, cytosolic C-terminal domain that could be activated by mM Ca^{2+}, corresponding to the concentration of extracellular Ca^{2+}. Since the predicted amino acid sequence of the protein contained seven putative transmembrane domains, it was suggested that this calcium receptor (CaR) functionally belongs to the well-characterized group of G protein-coupled receptors. The CaR is a glycoprotein that shares some homologies with glutamate receptors. The extracellular domain contains low-affinity Ca^{2+} binding sites characterized by clusters of negatively charged amino acid residues, typical for extracellular, Ca^{2+}-sensing proteins. CaR can be found in most cells throughout the body, but especially in cells of those organs that mainly control the level of calcium in the extracellular fluid, that is, in bone-forming and -resorbing cells, in parathyroid glands, and in cells of kidney and intestine. Long before the discovery of CaR, clinical observations of inheritable hypo- and hypercalcemic syndromes have been described that could now be linked to specific mutations of CaR, most of them in the extracellular calcium-sensing domain.

4 Signal Transduction Principles

4.1 General Properties

Cell-surface receptors can recognize extracellular signals (''primary messengers'') and multiply them into a cascade of intracellular events using a limited number of intracellular signal transducers, so-called ''second messengers.'' The most common intracellular signal multiplication system makes use of the phosphorylation/dephosphorylation of proteins or enzymes by activating a bunch of different kinases/phosphatases. To date, five classes of intracellular messengers are known:

1. cyclic nucleotides [cyclic adenosine 3′–5′ monophosphate (cyclic AMP); cyclic guanosine 3′–5′ monophosphate (cyclic GMP); cyclic ADP-ribose];
2. derivatives of phosphatidylinositol [inositolpolyphosphates, e.g. inositol-1,4,5-triphosphate (IP3), inositol-1,3,4,5-tetraphosphate (IP4), and diacylglycerol (DAG), stemming from the same precursor phosphatidylinositol-4,5- diphosphate (PIP2);
3. free Ca^{2+} ions;
4. gases such as nitric oxide (NO), probably also carbon monoxide (CO);
5. nicotinic acid adenine dinucleotide phosphate (NAADP).

The primary event in all signal-transducing pathways is the reception of an external signal by a specific receptor in the cellular membrane, activating a chain of reactions that will finally result in an intracellular response, that is, the cellular or plasma membrane is the main information barrier.

Ca^{2+} performs its second messenger function owing to changes in the distribution at the two sides of the membrane, which modulates its messenger function, in contrast to the metabolic synthesis and degradation of the other second messenger molecules. If the intracellular Ca^{2+} rises owing to the opening of Ca^{2+} channels upon receiving an extracellular signal, the ion will bind to specific proteins. This event will result in a conformational change enabling the triggering device to multiply the incoming signal. The occurrence of such Ca^{2+} binding regulatory proteins was first described in muscle tissues (i.e. troponin C) as mentioned before. The concept was later corroborated because of the detection of a variety of homologous proteins, as described in detail in Sect. 5.

The different second messengers are central components of intracellular control mechanisms. They are connected in their action through a complex network of feedback mechanisms. In addition, the interaction of polypeptide growth factors with their receptors is connected with signal transduction pathways. Thus, one of the earliest responses upon binding of growth factors to their receptors is a rapid increase in cytosolic free Ca^{2+} owing to receptor-activated, membrane-bound phospholipase C. This enzyme specifically cleaves phosphatidylinositol-4,5-diphosphate (PIP2) to release IP_3 and DAG, the former releasing Ca^{2+} from intracellular stores, whereas DAG activates the Ca^{2+}- and phospholipid-dependent protein kinase C.

4.2 Calcium Oscillations in the Cell

In 1986, Cobbold et al. made a striking observation: by monitoring the cytosolic calcium level of individual hepatocytes, they noticed that upon addition of vasopressin, a hormone known to mobilize intracellular calcium, the intracellular Ca^{2+} did not rise to a sustained level, but instead increased and decreased repetitively with a certain frequency (calcium spikes). They further observed that it was the frequency and not the amplitude of spiking that increased proportional to the rise in concentration of the added hormone, that is, an extracellular *analog* signal was converted into an intracellular *digital* signal. This seminal observation was soon confirmed in other laboratories on a variety of different cells indicating that calcium ''spikes'' and, in addition, calcium ''waves,'' the spatial counterpart of calcium spiking, are fundamentally important processes in signal transduction pathways. Two models describing these phenomena have been recently developed:

1. The IP_3–Ca^{2+} crosscoupling (ICC) model by Meyer & Stryer
2. The calcium-induced calcium-release (CICR) model by Berridge

Pivotal to both systems are positive feedback, cooperativity, deactivation, and reactivation of the process. The key element of the model described by Meyer & Stryer is the mutual reinforcement of the IP_3-induced Ca^{2+} release and the Ca^{2+}-stimulated IP_3 formation leading to a crosscoupling of two oscillating second messenger systems. By contrast, the

key assumption of the model proposed by Berridge et al. is the existence of two independent cytosolic Ca^{2+} stores: one that influences the cytosolic Ca^{2+} level owing to the IP_3-induced Ca^{2+} release, and the other that contains the Ca^{2+}-induced Ca^{2+} release channel. In this model, receptor activation leads to the formation of IP_3, which releases Ca^{2+} from IP_3-sensitive Ca^{2+} stores for inducing a constant efflux of calcium. The latter triggers Ca^{2+} from Ca^{2+}-sensitive stores, leading to an autocatalytic process in which the spiking characteristics depend on the frequency of the depletion and refilling of the Ca^{2+}-sensitive Ca^{2+} stores. Owing to the distribution of the storage systems over much of the cellular volume, calcium spiking leads to calcium waves (propagation rate 10–100 $\mu m\ s^{-1}$) as observed for many cells. Since the diffusion rate of IP_3 is 100 times faster than that of Ca^{2+}, calcium stores have to be much closer in space for the CICR model as compared to the ICC model to generate efficient calcium waves across the cell.

4.3
Calcium and the Cell Cycle

Calcium is one of the control elements of the cell division cycle (cdc) during proliferation of cells. Usually, there are three control points in a cell cycle: START, mitosis ENTRY, and mitosis EXIT. At all three points, a transient rise in the intracellular Ca^{2+} can be observed. The probable mediator of these Ca^{2+}-dependent cell cycle controls is calmodulin, a multifunctional intracellular calcium binding protein, as described later. It has been shown that overexpression of calmodulin leads to a reduction of the G1-phase in the cell cycle, whereas reduced calmodulin synthesis leads to arrest in G1 and mitosis EXIT. Of special interest is the observation that CaM-kinase activity is required for entry into mitosis. The relevant target for CaM kinase is a tyrosine phosphatase, known as cdc25 in yeast. This enzyme is activated because of phosphorylation by CaM kinase that enables it to dephosphorylate $pp34^{cdc2}$, a kinase involved in nuclear envelope breakdown, one of the key events during the cell cycle.

The essential role of calmodulin during cell cycle progression was demonstrated by Davis et al. for yeast. Evidence was provided that calmodulin was required for chromosome segregation and the polarized growth of bud formation. Interestingly, Davis identified two calmodulin targets that are important for chromosomal segregation, the spindle pole body protein SPC110 and the nonconventional myosin Myo2P. A mammalian homolog of SPC110 has recently been identified as a calmodulin target, supporting the earlier findings that calmodulin is associated with centrosomes during mitosis.

4.4
Calcium and Apoptosis

Apoptosis, or programmed cell death (PCD), is a process during which cells shrink and dissociate from their surrounding neighbors, their organelles retain in size, and in the nucleus chromatin forms dense aggregates on the nuclear membrane. Eventually, chromatin undergoes fragmentation, and the formation of membrane-enclosed structures termed *apoptotic bodies* that are extruded into the extracellular environment can be observed. On the other hand, necrotic cells swell, their mitochondria enlarge, the plasma membranes disrupture, but the nuclear changes are marginal.

PCD is an important mechanism during development that has emerged in multicellular organisms to remove unnecessary, damaged, or aged cells. Therefore, abnormal resistance toward apoptosis may lead to autoimmune diseases or cancer, whereas uncontrolled enhancement of apoptotic processes could favor chronic pathologies such as neurodegenerative diseases (e.g. dementia of the Alzheimer type) or immune deficiencies such as AIDS.

A number of highly conserved proteins, called *death proteins*, are involved in the complex apoptotic pathways by either causing or preventing cell death. This was mainly due to detailed studies of the nematode *Caenorhabditis elegans*. During development, 131 of the total 1090 cells of *C. elegans* are predestined to die. This apoptotic process is controlled by the coordinated expression of the death proteins ced-3, ced-4, and ced-9, some of which belong to the highly conserved family of cysteine proteases, called *caspases*, others to oncogenes such as bcl-2.

Work in a number of different labs has demonstrated that alterations in intracellular Ca^{2+} homeostasis are commonly involved in promoting apoptosis. One aspect of the function of bcl-2 involves preventing these alterations. So it has been demonstrated that sustained levels of Ca^{2+} in mitochondria can be significantly lowered by the expression of bcl-2 and that bcl-2 can block the depletion of endoplasmic reticular Ca^{2+} stores. In addition, it has been shown that IP_3-dependent Ca^{2+} release is essential for triggering apoptosis. One of the consequences may lead to the activation of Ca^{2+}-dependent endonucleases that are responsible for the cleavage of DNA linker regions between nucleosomes, leading to the frequently observed DNA laddering during apoptotic processes.

Another interesting link between Ca^{2+} and apoptosis was recently reported by the discovery of a new member of a Ca^{2+} binding protein of the EF-hand type, called ALG-2, which was linked to apoptosis (see below). It was observed that T-cell hybridomas depleted of ALG-2 were protected against PCD induced by a variety of stimuli including dexamethasone and Fas/CD95 triggering. Evidence was provided that members of the ICE protease family were activated upon stimulation by either Fas/APO-1 antibodies or dexamethasone in ALG-2 depleted cells, but progression of cell death was impaired indicating that ALG-2 is necessary for the apoptotic function of ICE/Ced-3 proteases. However, later it was reported that mice lacking the *ALG-2* gene not only developed normally but it was also observed that in T cells obtained from those mice, apoptotic processes could be induced indicating that ALG-2 is not essential for apoptosis.

By using a similar functional selection strategy of cloning to identify genes linked to PCD, a *d*eath *a*ssociated *p*rotein (DAP) was identified as a kinase, therefore called DAP-kinase. This protein turned out to be a Ca^{2+}-calmodulin-dependent kinase of 160 kDa. It is specific for phosphorylating serine/threonine residues, and contains a number of other domains such as ankyrin repeats, P-loops, cytoskeleton binding domains, and death domains. It was demonstrated that the enzyme phosphorylated myosin light chains in a Ca^{2+}-calmodulin-dependent manner and is associated with the cytoskeleton of the cells. The latter observation could be of special interest since changes in the actin microfilament of the cytoskeleton organization preceded the nuclear condensation and segmentation in response to interferon-γ-stimulation or DAP-kinase overexpression.

5
Intracellular Calcium Binding Proteins

5.1
The EF-hand Protein Family

As pointed out before, the concentration of the intracellular Ca^{2+} in eucaryotic cells is closely regulated to remain below 5×10^{-7} M in a resting cell, whereas outside cells [Ca^{2+}] is 10^{-3} M, resulting in a steep concentration gradient across the plasma membrane. The intracellular level of Ca^{2+} can transiently increase owing to a response to extracellular signals. In order to function as a second messenger, the Ca^{2+} signal is transduced by a variety of Ca^{2+} binding proteins. In contrast to the extracellular, low-affinity Ca^{2+} binding proteins, the intracellular proteins bind Ca^{2+} with high affinity owing to a sequential arrangement of the amino acids ligating calcium in a loop flanked by two helical segments. This common helix-loop-helix Ca^{2+} binding motif, also known as the EF hand as coined by Kretsinger, is an important entity of the intracellular Ca^{2+} receptor proteins for triggering cellular responses. The helix-loop-helix motif can be present in several copies in these proteins. The number of the latter is steadily increasing, (to date more than 600 have been described, but for most of them a precise function is not known yet).

In 1973, Kretsinger and Nockolds reported the crystal structure of parvalbumin. The protein consists of two homologous calcium binding domains each of which contains two α-helices perpendicular to each other enclosing a Ca^{2+} binding loop, the well-known ''EF-hand''. Parvalbumin thus became the prototype of numerous Ca^{2+} binding proteins with similar structural properties, such as calmodulin, troponin C, recoverin, S100 proteins, and others. To date, more than 50 structures of EF-hand proteins are known. All EF-hand domains show a pentagonal-bipyramidal coordination of the Ca^{2+} ion in the loop flanked by the two approximately perpendicular helices. The residues forming the ligands to Ca^{2+} are highly conserved within a contiguous sequence of 12 residues spanning the loop and the beginning of the second helix. Loop residues in positions 1, 3, 5, and 12 contribute monodentate (1, 3, 5) or bidentate (12) Ca^{2+} ligands through side-chain oxygens and residue 7 through its backbone carbonyl oxygen. Therefore, an invariant glycine residue is in position 6 to permit the sharp bend necessary to ligate Ca^{2+} through the oxygen of a side chain (5) and a backbone carbonyl (7). Residue 9 provides an additional ligand, either directly through an oxygen of its side chain or indirectly via a water molecule. In position 1 of the loop, usually an aspartate is located, whereas in position 12, glutamic acid is invariant. The latter has two reasons:

1. both oxygens of the side-chain carboxylate ligate to calcium and
2. glutamic acid has α-helix-inducing propensity.

The Ca^{2+} binding domains usually occur in pairs stabilized by hydrogen-bond bridges between the central residues of adjacent loops that form a minimal antiparallel β-sheet. Owing to these pair-forming Ca^{2+} binding domains, the Ca^{2+} affinity to these sites and the cooperativity of binding is enhanced. Calmodulin and troponin C contain four Ca^{2+} binding sites. Both proteins display Ca^{2+} binding characteristics compatible with a ''pair-of-pairs'' model of EF-hands, that is, the two globular domains at the N- and C-terminal

site each contain a pair of EF-hands, and the domains are connected by a long central helix providing a dumbbell-shaped appearance as revealed by crystal-structure determination. The N- and C-terminal domains bind calcium cooperatively, the C-terminal domain with higher affinity. Recent multinuclear magnetic resonance experiments of the Ca^{2+}-bound form of calmodulin corroborated the general validity of the dumbbell-shaped structure in solution, but indicated the high degree of flexibility of the central part of the helix that is also supported by a high B-factor (temperature-factor) in that region in the crystal structure. This flexibility in the center of the molecule is an important property for the interaction with targets. Upon binding of calcium and subsequent conformational change of the protein, the extended dumbbell-shaped form of calmodulin in the absence of a target is transformed into a more compact form upon interacting with a target. By bending the central helix and bringing the two domains close together, thereby engulfing the peptide representing the CaM binding domain is documented by numerous examples, some of which will be discussed below in more detail (see Fig. 2).

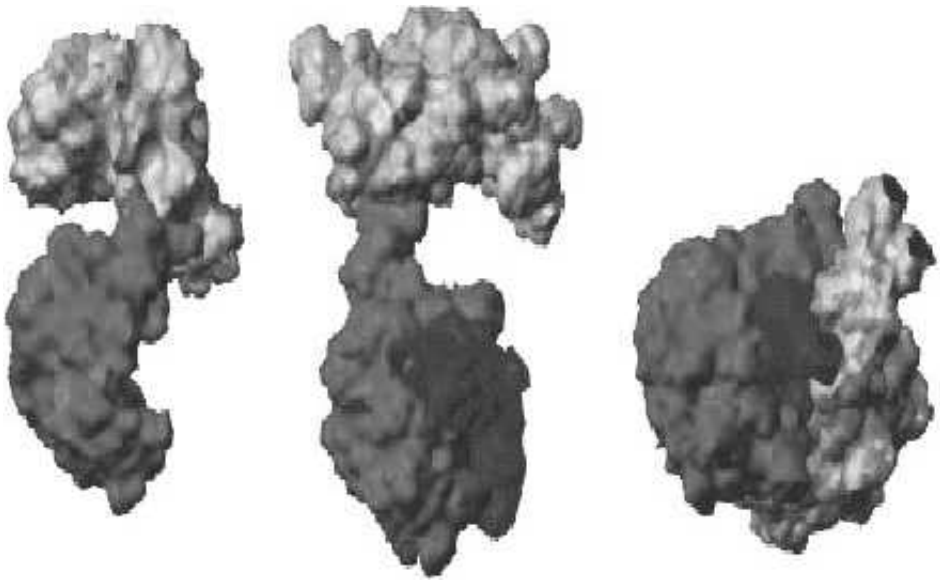

Fig. 2 Surface representation of calcium-bound calmodulin (CaM) and its different binding modes to peptides. The N-terminal half of CaM is in orange, the C-terminal half is in red, and the peptides are in blue. The orientation of the C-terminal half of CaM is the same in all cases. (a) Crystal structure of calcium-bound CaM. (b) Solution structure of the CaM/C20W complex showing that the peptide C20W, corresponding to the N-terminal portion of the CaM binding domain of the plasma membrane Ca^{2+} pump, but lacking the C-terminal hydrophobic anchor residue, binds only to the C-terminal half of CaM. (c) The solution structure of CaM/M13 shows a compact globular complex involving both C- and N-terminal halves of CaM in binding the peptide M13 corresponding to the CaM binding domain of MLCK. 5.1.1 Calmodulin and its Targets

5.1.1.1 Structural principles of Calmodulin-target interactions

As pointed out before, calmodulin (CaM) undergoes a profound conformational change upon binding of Ca^{2+} to the different EF-hand loops of the protein. As a consequence, deep hydrophobic clefts are built that are a prerequisite for the interaction with targets. In the absence of a target, the N-terminal and the C-terminal halves of CaM behave as independent structural units in solution that are linked by a flexible tether. The latter is part of the seven-turn central helix observed in the crystal structure of the protein.

CaM binding sequences of different targets reveal similar properties (see Table 1). They are composed of short peptides with an average length of 20 to 30 amino acids that have the propensity to form a basic amphiphilic α-helix. Several three-dimensional structures of complexes between calmodulin and target peptides representing binding domains of different CaM-dependent kinases, such as skeletal muscle and smooth muscle myosin light chain kinase (MLCK), CaM-dependent protein kinase II, and CaM-dependent protein kinase kinase, have been solved by either NMR or X-ray crystallography. These structures share some common structural features:

1. Calmodulin, which usually has an extended, dumbbell-type shape, is collapsed to a globular structure wrapped around the target peptide
2. The peptide is located in a hydrophobic channel passing through the center of the globular molecule
3. Two hydrophobic residues of the binding peptide spaced by a defined number of residues are essential for the interaction with CaM (see Table 1).
4. The peptides interact with CaM in an antiparallel manner, that is, the N-terminal half of CaM binds the C-terminal part of the peptide and *vice versa*. Structural examples of some CaM-target interactions are presented in Fig. 2 showing the structures of calmodulin in its Ca^{2+}-bound form and how it interacts with the CaM binding domains of the plasma membrane calcium pump and of MLCK.

An exception to rule (4) was recently reported by Ikura et al. who solved the structure of the complex of CaM bound to the peptide of the binding domain of CaMKK by NMR. In this complex, the peptide comprises unusual structural properties, that is, only the N-terminal

Boxed hydrophobic residues represent the critical anchoring amino acids of the different CaM binding domains.

half forms an α-helix, the C-terminal half is a hairpin loop folding back on itself. In addition, the peptide is oriented in a parallel fashion relative to the two halves of CaM.

Interestingly, recent experiments with small-angle X-ray scattering and neutron scattering by the group of Trewhella provided evidence that also when CaM is complexed to an intact enzyme, that is, MLCK, CaM undergoes a conformational collapse identical to that observed with the peptide corresponding to its binding domain.

The first crystal structure of a CaM-dependent enzyme, CaM-dependent kinase I (CaMKI), obtained in the absence of CaM, that is, in the autoinhibited state, supports the view that the C-terminal regulatory domain forms a helix-loop-helix segment that interferes with the two domains of the catalytic core, that is, with the binding site of peptide substrates and with the ATPbinding site. An interesting feature of this structure is the striking observation that the N-terminal part of the CaM binding domain is accessible for an initial interaction with CaM. This part comprises the loop region of the regulatory domain including the conserved tryptophan that provides the hydrophobic anchor for the C-terminal half of CaM. Furthermore, it was recently postulated that the interaction between the C-terminal half of CaM and the CaM binding domain of a CaM-dependent enzyme is necessary, and sometimes already sufficient, to release the autoinhibited state of the enzyme. This view was based on the three-dimensional NMR structure of the complex between CaM and the N-terminal part of the binding domain of the plasma membrane calcium pump (Fig. 2b), a view that is supported by recent structural studies on MLCK indicating that initial binding of CaM to MLCK occurs already at substoichiometric Ca^{2+} concentrations, that is, at about 2 moles of Ca^{2+}/mol of CaM.

Calmodulin is a very versatile modulator protein interacting with a variety of different enzymes such as adenylate cyclases, cyclic nucleotide phosphatases, NO synthases, protein kinases, and others. One of the best-studied families of CaM-dependent enzymes is the CaM-dependent protein kinases, which will be outlined in more detail.

5.1.1.2 Calmodulin-dependent Kinases

Calmodulin-dependent protein kinases can be divided into two categories

1. Kinases dedicated to single substrates, called *monosubstrate kinases*. Examples of this class are the myosin light chain kinase (MLCK), the phosphorylase kinase, and CaM-dependent kinase III or elongation factor 2 kinase. MLCK will be described in more detail.
2. Kinases dedicated to different substrates, called *multisubstrate kinases*. Examples of this class are CaM kinase I, II, and IV, and the CaM kinase kinase, activating CaMKI and IV.

5.1.1.2.1 Monosubstrate CaM Kinases

Myosin Light Chain Kinase (MLCK) The most extensively studied calmodulin-dependent enzyme is the myosin light chain kinase (MLCK). This enzyme catalyzes the phosphorylation of a specific serine residue in the N-terminal portion of the myosin II regulatory light chains. Two types of MLCK exist that differ genetically, biochemically, and physiologically and that are expressed in two different types of muscles: the MLCK of skeletal muscles (skMLCK) and of smooth or nonmuscle cells (smMLCK). The two different MLCK

enzymes are encoded by different genes. SkMLCK corresponds to a molecular mass of 65 kDa, whereas the expression pattern and genomic organization of sm/nm MLCK is more complex. This is due to alternative splicing that results in different isoforms with significantly different molecular weights, ranging between 150 and 200 kDa owing to different lengths of their amino termini.

To date, the regulatory myosin light chain is the only established substrate of MLCK. In smooth muscles, the Ca^{2+}-dependent trigger of muscle contraction is directly mediated by the phosphorylation of the light chain by MLCK thus removing the inhibition of the myosin ATPase. In skeletal muscle, however, the actomyosin ATPase is regulated by binding of Ca^{2+} to troponin C, the regulatory calcium binding protein in the troponin complex. A possible function of MLCK in skeletal muscle is to modulate the rate of enhancement and extent of isometric contraction of the muscle.

The substrate specificity of MLCK is very strict. Substrate recognition is basically dependent on the appropriate location of at least four basic residues over a more extended region N-terminal of the phosphorylated serine residue. Calmodulin-dependent enzymes are activated by disrupting an autoinhibitory segment that interacts with the catalytic core of the enzyme and thus deinhibiting the enzyme. This concept was first developed and verified for the cAMP-dependent protein kinase (PKA) that could be blocked by an endogenous inhibitor (PKI) competing with the substrate about the substrate binding site, thus serving as a pseudosubstrate. MLCK is the CaM-dependent enzyme that has been studied very thoroughly by Kemp et al. to provide evidence for the existence of a pseudosubstrate to serve as an autoinhibitory domain in MLCK. This view gained further support by the finding that controlled proteolysis at the C-terminal end of MLCK generated a constitutively active fragment independent of calmodulin activation, that is, the autoinhibitory domain was removed.

5.1.1.2.2 **Multisubstrate CaM Kinases** Four different enzymes of calmodulin-dependent protein kinases fall into the class of multifunctional or multisubstrate kinases, CaMKI, CaMKII, CaMKIV, and CaMKK, the activating kinase of CaMKI and IV. This class can be subdivided into CaMKII on one side and CaMKI, CaMKIV, and CaMKK on the other for two reasons: (1) CaMKI, CaMKIV, and CaMKK act as monomeric proteins, whereas CaMKII is a multimeric enzyme composed of up to 12 subunits; (2) CaMKI and CaMKIV are activated by another calmodulin-dependent protein kinase, that is, by CaMKK. Whether CaMKK itself is also activated by an upstream acting kinase is not clear at the moment, but there are indications that this indeed might be the case. In contrast, CaMKII is activated by autophosphorylation. Therefore, the latter is discussed separately from CaMKI, CaMKIV, and CaMKK.

CaMKII Calmodulin-dependent protein kinase II (CaMKII) represents a family of closely related protein kinases with broad substrate specificity. This class of protein kinases is involved in cellular metabolism, neurotransmitter release, cytoskeletal structure, gene expression, cell cycle control, and, more recently, in long-term potentiation and depression (LTP and LTD), functions that are thought to be involved in memory and learning.

Structural Organization The holoenzyme is an oligomeric complex of 6 to 12 subunits with a total molecular mass ranging from 300 to 700 kDa, which can be either a homomultimer or a heteromultimer. According to the amino acid sequences, the different isoforms are closely related to each other and reveal the segmental organization typical for CaM-dependent protein kinases, consisting of catalytic, regulatory, variable, and association domains on the same polypeptide chain.

The overall structure of the catalytic domain of CaMKII is likely to be bilobal, as expected for all CaM-dependent protein kinases, on the basis of the crystal structure of CaMKI. Catalysis takes place within a cleft between the two lobes orienting the consensus sequence of the substrate in such a way that the basic residue(s) in proximity to the serine/threonine residue that should be phosphorylated could interact with the conserved polar residues located on the surface of the large lobe. The small lobe contains a lysine residue that is essential for ATP binding, that is, if mutated to a methionine renders the kinase inactive.

Regulation of the Catalytic Activity Since CaMKII has a broad range of substrates, the consensus sequence for substrate determination is less strict than that described for MLCK before. Basically, an arginine at the P−3 position, the phosphorylated serine/threonine being P(0), is the only essential requirement for a multifunctional kinase such as CaMKII. In addition, hydrophobic residues are preferred at P−5 and P+1. Downstream of the catalytic domain, the autoinhibitory, the CaM binding, and the association domains are located, interspersed with variable domains.

As discussed in detail before, CaM activates its targets by wrapping around the binding domain thereby releasing the enzyme from its autoinhibitory state. In the case of CaMKII, the three-dimensional structure of the complex between CaM and a peptide representing the CaM binding domain of CaMKII has been determined by X-ray crystallography. This complex also shows the general feature observed for similar CaM–peptide complexes, that is, CaM is collapsed to a globular structure engulfing the helical peptide that is fixed by numerous hydrophobic and electrostatic interactions. An important difference between the interactions of CaM with CaMKII and MLCK, respectively, is the different affinity of CaM for the two enzymes, that is, the affinity for CaMKII is much lower (K_{act} 20–100 nM) than that for MLCK (K_{act} 1 nM). However, the affinity for CaMKII can be substantially enhanced (>1000-fold) by autophosphorylation of Thr286 resulting in a significant lowering of the CaM off-rate from the complex, a phenomenon termed *calmodulin trapping* that might have some important implications for the function of the enzyme as discussed below.

CaMKII and Neuronal Plasticity Cyclic cellular depolarization or hormonal stimuli can trigger a series of calcium pulses inside cells. In neurons, these Ca^{2+} oscillations can be used to modulate synaptic activity and strength with subsequently increased release or resynthesis of neurotransmitters or other cellular activities. The coordinator of at least some of these activities appears to be CaMKII; however, the question is, ''Is CaMKII able to decode Ca^{2+} oscillations, and if yes, how?''

The hippocampus has been used to study processes in which high-frequency

stimulation leads to long-term potentiation (LTP) and low-frequency stimulation to long-term depression (LTD). These processes have been implied as important models for studying spatial learning and memory storage. It was also reported that both processes are induced by an increase in intracellular Ca^{2+} in the postsynaptic neuron concommitant with a rise in CaMKII activity and phosphorylation of synapsin I.

An important link has been made between LTP and some forms of learning, and its dependence on CaMKII by gene-targeted disruption of CaMKIIα, by the group of Tonegawa. These studies provided evidence that those mice that developed normally were not only impaired in spatial learning but also that induction of LTP was blocked in hippocampal slices from those mice.

Recently, De Koninck and Schulman provided direct evidence that CaMKII indeed can decode the frequency of Ca^{2+} pulses. Owing to the complex activation pattern of CaMKII by CaM, autophosphorylation, and subsequent CaM trapping, the enzyme can become autonomous. Autophosphorylation is an intersubunit reaction between proximate subunits in which CaM not only activates the ''kinase'' subunit but also presents the ''substrate'' subunit for phosphorylation. Subsequently, the kinase is transformed into the ''trapped'' state, that is, a cooperative, positive feedback loop resulting in a short molecular ''memory'' that could enable the enzyme to respond to digital and cyclic activation associated with Ca^{2+} oscillations. In simulation calculations, it was predicted that repetitive Ca^{2+} pulses lead to recruitment of CaM, autophosphorylation and trapping of CaM, establishing a threshold frequency at which the activity of the enzyme is sustained. These predictions were exactly confirmed by the experiments of De Koninck and Schulman who could demonstrate that, independent of the Ca^{2+}-CaM pulse duration, the autonomous activation of CaMKII increased steeply as a function of frequency. On the other hand, once a threshold value was achieved, it was possible to maintain the response level with signals of substantially lower frequency.

CaMKI and IV In contrast to CaMKII, which is a multimeric protein, CaMKI and CaMKIV are monomeric enzymes. CaMKI is, like CaMKII, ubiquitously expressed, whereas the tissue distribution of CaMKIV is restricted to nervous tissues, the thymus, particularly T lymphocytes, the bone marrow, keratinocytes, testis, and ovary. Both enzymes are activated not only by autophosphorylation but also by another CaM-dependent protein kinase, the CaM kinase kinase (CaMKK).

The Crystal Structure of CaMKI In 1996, the group of Kuriyan reported the crystal structure of CaMKI in the autoinhibited state, that is, in the absence of CaM. This is the first three-dimensional structure of a calmodulin-dependent enzyme determined at high resolution, as mentioned before. The crystal structure of CaMKI provided evidence of significant contacts between the autoinhibitory sequence and the catalytic core of the kinase, thereby supporting the pseudosubstrate model for activation of calmodulin-dependent protein kinases. Another important result was the finding that Trp303 corresponding to the first anchoring residue of the CaM binding domain (see Table 1) lies on the surface of the protein. This arrangement makes it very likely that CaM could first bind to the exposed Trp303 and subsequently release the β-strands of the ATP

binding domain from their interaction with the regulatory segment comprising the core of the CaM binding domain. Such an arrangement could be of general relevance for the activation mechanism of CaM-dependent enzymes. The structure further suggests that binding of CaM and subsequent reorientation of the ATP binding domain would open up the substrate binding domain that would permit Thr177 to be accessible for the activating CaMKK.

Regulation of Activity The regulation of the activity of CaMKI and CaMKIV is a rather complex process and involves three major steps:

1. Binding of Ca^{2+}/CaM to the enzyme
2. Phosphorylation of either Thr177 (CaMKI) or Thr196 (CaMKIV) located in the activation loop of the kinases by CaMKK
3. Autophosphorylation of serine residue(s) at the N-terminus of the enzyme

CaMKII on one hand and CaMKI and CaMKIV on the other are activated by different mechanisms. As discussed before, CaMKII is a multisubunit, homo- or hetero-oligomer enzyme complex that is activated by autophosphorylation between two neighbouring subunits. On the other hand, CaMKI and CaMKIV do not seem to multimerize, and both enzymes are activated by CaMKK; whether both are activated by the same kinase kinase or by different enzymes is not entirely clear. In CaMKIV, the critical residue phosphorylated by CaMKK is Thr196, which is located in the activation loop of the kinase and is homologous to Thr177 in CaMKI. Accessibility of the two threonine residues is brought about by the binding of calmodulin, that is, binding of calmodulin not only releases autoinhibition of I or IV but also enables the enzymes to be phosphorylated at this critical residue. This phosphorylation results in a 10- to 20-fold activation in the case of CaMKIV. Furthermore, it was reported for CaMKIV that Ser11 and Ser12 could be autophosphorylated in a slow process as indicated before, but CaMKK could considerably enhance this process by phosphorylating Thr196.

CaMKIV and Ca^{2+}-dependent Gene Expression One of the consequences of elevated calcium in the cell, especially in the nucleus, is the induction of gene expression. Since transcription factors such as CREB, CREMτ, ATF-1, SRF, and ETS-1 are among the best substrates for CaMKIV, and CaMKIV has been localized to the nucleus, the enzyme could have direct access to transcription factors to regulate their function in a Ca^{2+}-dependent manner. Thus, it has been shown in different cell lines that CaMKIV is involved in the regulation of expression of immediate early genes (IEGs) either through CREB or through SRF.

Originally, CREB was identified as a transcription factor induced in a cAMP-dependent process, but later studies demonstrated that several kinases activating CREB phosphorylated the transcription factor at the same serine residue, Ser133. In contrast to CaMKIV, CaMKII phosphorylates next to Ser133 also Ser142, which has an inhibitory effect on gene expression.

CaM-dependent Protein Kinase Kinase (CaMKK) As indicated before, CaMKI and IV are activated by calmodulin-dependent protein kinase(s), the CaMKK. Two isoforms of CaMKK are known to date, α and β which are encoded by different genes. Both isoforms are organized

similar to other CaM-dependent kinases with catalytic, autoinhibitory, and CaM binding domains. In addition, CaMKK contains an unusual arginine–proline rich insert within the N-terminal part of its catalytic domain that might be important for the recognition of CaMKI and IV as substrates since deletion of these inserts abolishes its activation potential toward CaMKI and IV.

CaMKK can be found both in the cytoplasm and in the nucleus; the latter is important for the activation of CaMKIV that is mainly responsible for the Ca^{2+}-dependent gene expression. In this context, it is interesting to note that the distribution of βCaMKK in the brain is much more similar to CaMKIV, and that of αCaMKK follows the distribution of CaMKI, suggesting that βCaMKK could be the actual activator of CaMKIV, whereas αCaMKK would be that of CaMKI. Nevertheless, both isoforms of CaMKK can activate CaMKI and IV with the same efficiency, but whether there exist more specific isoforms and whether there are additional kinases further upstream like in the MAP-kinase cascade is not known to date.

5.1.2 Neuronal Calcium Sensors

A group of EF-hand proteins that has recently received attention is that of the neuronal calcium sensors (NCS). They are divided into five subfamilies. Two of them are expressed in retinal photoreceptors, called recoverins and guanylate cyclase-activating proteins (GCAPs), the three others frequenins, visinin-like proteins, and the Kv channel–interacting proteins. Recoverins and GCAPs have antagonistic roles in phototransduction: recoverin inhibits rhodopsin kinase and GCAPs activate guanylate cyclase. The other three NCS families are supposed to regulate the release of neurotransmitters, the biosynthesis of polyphosphoinositides, the metabolism of cyclic nucleotides, or the activity of Kv channels. Most NCSs are N-terminally myristoylated, favoring interaction with membranes (or target proteins) in a Ca^{2+}-dependent manner. Thus, the Ca^{2+}-dependent myristoyl switch could be a means to compartmentalize signaling cascades in neurons or to transduce Ca^{2+} signals to the membranes.

5.1.3 S100 Proteins

The multigenic family of the so-called S100 proteins (named because they are soluble at 100% ammonium sulfate solution) is growing steadily, and possible functions have been implicated in intracellular and extracellular regulatory activities. To this family belong proteins that are involved in cell cycle control (e.g. calcyclin) or can display neurite growth factor activities such as the S100β dimer. S100B was the first member of the EF-hand family that is secreted to perform its extracellular function as a growth factor. The latter function is exclusively connected with the β-isoform and only so if it can form a dimer. Mutation of one of the cysteine residues necessary for the dimer formation leads to the loss of this function. Recently, it has been suggested that the S100β dimer carries out its growth factor function through the RAGE receptor (receptor for advanced glycation end products).

In general, members of the S100 protein family have low molecular weights (M_r between 9 and 14 kDa). They usually function as homodimers, but some also as heterodimers. Of special note is the finding reported by Heizmann et al. that in human S100A1–S100A13 are clustered on chromosome 1 (1q21) within 5 Mb, but a common regulation of expression has not been observed.

5.1.4 The Penta EF-hand Family

The EF-hand motifs in Ca^{2+} binding proteins are usually tandemly repeated. Owing to the recent determination of the X-ray structure of the small subunits of the calcium-dependent protease calpain, it was recognized that also uneven numbers of EF-hand domains may exist in proteins. By comparing the primary structures of a number of different calcium binding proteins, Maki et al. identified several proteins that, like calpain, contained five EF-hand domains, and therefore introduced the name ''penta EF-hand family'' or PEF family for this subgroup of EF-hand-containing proteins. Members of this family include calpain, sorcin, grancalcin, peflin, and ALG-2; the latter was originally identified as ''**a**poptosis-**l**inked **g**ene''. Characteristic to all the members of this family is a two–amino acid insertion into the loop of the fifth EF-hand domain, and therefore, at least under physiological conditions, may not bind calcium anymore. Instead, the fifth domain may serve as a dimerization domain, as originally observed in the calpain structure and later confirmed by solving the structure of ALG-2 and grancalcin.

Proteins of the PEF family have been quite conserved during evolution; homologs have been found in invertebrates, plants, fungi, and even in protists. On the basis of comparison of the gene structures, PEF proteins can be classified into two groups: group I contains ALG-2, peflin, and their homologs, and group II is composed of calpain, sorcin, and grancalcin.

As indicated before, calpain is a calcium-dependent, intracellular protease, of which two major isozymes exist, calpain I and II, which differ in their Ca^{2+} dependence; that is, calpain I or μ-calpain is activated by micromolar calcium concentrations, whereas calpain II or m-calpain needs millimolar calcium to be activated *in vitro*. Both isoforms exist as heterodimers consisting of a large subunit (80 kDa), containing the catalytic site, and of a small regulatory subunit (30 kDa). Recently, Suzuki, Bode et al. determined the structure of the full-length, heterodimeric human calpain II in its Ca^{2+}-free form as shown in Fig. 3: the two subdomains IIa and IIb of the large subunit comprising the catalytic site are rotated against each other, disrupting the active and the substrate binding sites, which would explain the inactivity of calpain in the absence of calcium. Surprisingly, the group of Davies who determined the structure of calpain I in the Ca^{2+}-bound form suggested that the cooperative binding of Ca^{2+} to two non-EF-hand-type Ca^{2+} binding sites derived from two different peptides aligned the active site cleft and converts the protein into an active enzyme, and Ca^{2+} binding to the EF-hand-type binding sites would contribute to the Ca^{2+} sensitivity of the enzymes, as documented by mutational analysis. In addition, both isoforms of calpain are maintained in an inactive form because of the interaction with an endogenous inhibitor, calpastatin, until external signals activate the protease.

Increasing evidence indicates that calpain is involved in the regulation of basic cellular processes such as cell proliferation, differentiation, and apoptosis owing to cytoskeletal remodeling, which, under pathological conditions, could contribute to tissue damage in heart and brain ischemias as well as neurodegeneration in Alzheimer's disease.

ALG-2 was originally identified as a gene linked to apoptosis. It is a 22 kDa highly conserved and ubiquitously expressed protein that forms dimers through the fifth EF-hand, as documented by the crystal structure. This could provide a new

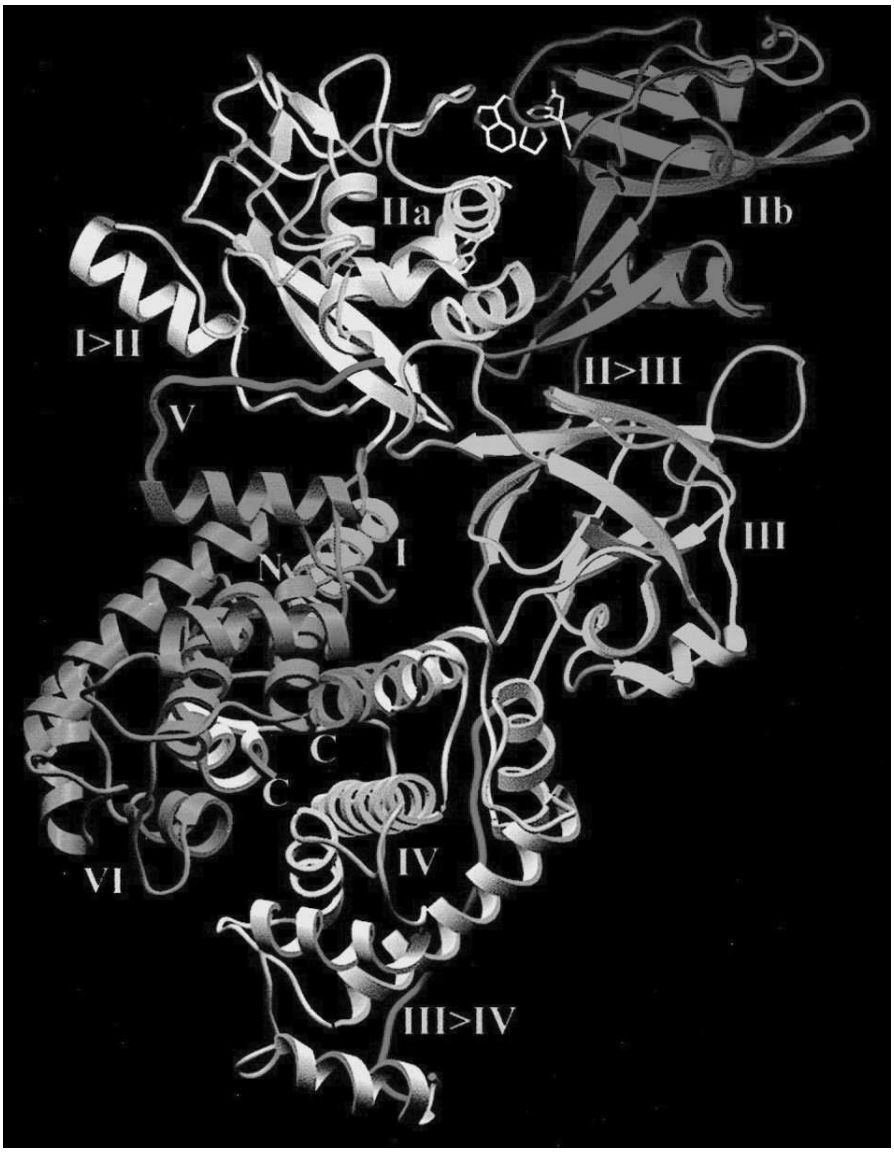

Fig. 3 Ribbon structure of human m-calpain in the absence of calcium. The 80 kDa large subunit starts in the molecular center, folds into the surface of the dIIa subdomain, forms the catalytic domain dII, builds domain dIII, runs down, and forms the right-side calmodulin-like domain dIV. The 30 kDa small subunit becomes visible before forming the left-side calmodulin domain dVI. (Reprinted with permission from Strobl et al., 2000, *Proc. Natl. Acad. Sci. USA*, **97**, 588–592.)

interface for the interaction with possible targets of which a number of different proteins such as AIP or Alix have been identified, which in Xenopus is involved in the maturation process of oocytes, peflin, and different annexins. All these targets interact with ALG-2 in a calcium-dependent manner indicating that ALG-2, like calmodulin, may have calcium sensing, that is, signal transduction–regulating properties. Therefore, the involvement in apoptosis, which gave the protein its name, would be one but not the exclusive signal transduction pathway. In addition, as mentioned before, it has been shown that ALG-2 is not essential for apoptotic responses since by using T cells from ALG-2-deficient mice, apoptotic stimuli could be induced by either stimulating T-cell receptors (TCR), Fas/CD95, or by glucocorticoids.

Recent experiments carried out in our lab indicated that ALG-2 may not only be involved in apoptotic processes but may also play a role during cell proliferation. A significant nuclear concentration of ALG-2 was found in cells prior to cell division, in addition to a significant increase in ALG-2 expression in highly proliferative cells obtained from cancerous tissues, especially evident for those from metastatic tissues. ALG-2 may thus be an important modulator involved in the cellular decision between cell proliferation and cell death.

5.2 Non-EF-hand Ca^{2+} Binding Proteins

5.2.1 Annexins

Next to the family of the EF-hand-containing Ca^{2+} binding proteins, another intracellular Ca^{2+} binding protein family became known in recent years. These soluble, amphipathic proteins bind to membranes containing negatively charged phospholipids in a Ca^{2+}-dependent manner and are therefore called *annexins*. They are widespread in the animal and plant kingdom and have been claimed to be involved in a variety of cellular functions such as interaction with the cytoskeleton, membrane fusion, anticoagulation, signal transduction, or phospholipase inhibition. The primary structure of the annexins known to date contain 4 or 8 conserved repeat units of about 75 amino acids in length, which are separated by intervening sequences of variable length. For some of these proteins, the crystal structure is known. The most detailed studied protein, annexin V, is almost entirely α-helical. It consists of five α-helices bundled into a right-handed super-helix. On the basis of this structure, it was proposed that annexin V functions as a calcium channel, and some experiments using a reconstituted system seem to support a voltage-gated mechanism. In contrast to the EF-hand-containing Ca^{2+} binding proteins, the ligands coordinating calcium in the annexins are not adjacent in sequence. Three calcium binding sites seem to exist in annexins, two invariably in repeats II and IV, one in either repeat I or III. As indicated for the EF-hand proteins, also in the annexins, calcium is hepta-coordinated with ligands organized in a pentagonal bipyramid. The ligating oxygens mainly stem from peptide carbonyls or water molecules.

An interesting feature of annexin I and II is their phosphorylation by either the EGF receptor kinase or the *src*-encoded tyrosine kinase respectively suggesting their involvement as coupling factors between growth factor receptors and their cellular targets. Furthermore, annexin II has been found to form stable heterotetrameric complexes with p11, a member of the S100

family, thereby increasing its Ca^{2+} sensitivity by 3 orders of magnitude. However, formation of such a complex interferes with the phosphorylation of annexin II by different kinases.

5.2.2 Gelsolin

Gelsolin is a multifunctional protein binding actin in a Ca^{2+}-dependent manner. It can also nucleate actin polymerization by binding two actin monomers. Alternative transcription initiation and selective RNA processing produces two isoforms from the same gene; one isoform is located intracellular and the other extracellular. The intracellular gelsolin is involved in cell motility–regulating actin function, whereas extracellular gelsolin can act as an actin-scavenging system to prevent the polymerization of actin released after cell death.

Gelsolin consists of 6 repeat units (G1 to G6) containing 120 to 150 amino acids. The units are organized in 2 clusters of similar architecture and are connected by a flexible linker of about 50 amino acids that may be cleaved by caspase-3. One repeat unit, G1, has been crystallized in a complex with actin. It is organized in a central four-stranded β-sheet motif faced on one side by a four-turn α-helix parallel to the strands and on the other side by a shorter α-helix perpendicular to the strands. The longer helix also serves as the binding partner to a cleft between two actin subdomains. The G1-actin-complexed domain comprises two Ca^{2+} binding sites.

The regulation of gelsolin activity by Ca^{2+} has recently been proposed. This was made possible by comparing the Ca^{2+}-free structure of nonactive gelsolin with the active, Ca^{2+}-bound gelsolin complexed to actin. In the absence of Ca^{2+}, the six repeat units of gelsolin provide a very compact globular structure, thus blocking the actin-binding helices of the appropriate subdomains. By binding of Ca^{2+} to gelsolin, the N- and C-terminal halves of the protein, that is, G1 to G3 and G4 to G6, become separated, thereby unmasking the actin binding sites, and hence permit binding to actin strands.

5.2.3 C_2-domains

Synaptotagmin, a transmembrane protein of synaptic vesicles, is believed to act as the major Ca^{2+} sensor of exocytosis and neurotransmitter release. The cytoplasmic region of synaptotagmin contains two C_2 domains (C_2A and C_2B) that are Ca^{2+} binding domains of non-EF-hand character. These domains have been first described in protein kinase C by Nishizuka, and have been suggested to be responsible for binding to membranes in response to Ca^{2+}. The C_2 domain consists of a β-sandwich of two four-stranded β-sheets. The β-strands are connected by loops, some of which bind clusters of Ca^{2+} ions, primarily through oxygens of aspartate side chains. Sequence homology and structural similarity among C_2 domains of different proteins are high for the β-strands, which probably constitute scaffolds to support the Ca^{2+} binding loops. A recent detailed mutational analysis of synaptotagmin in *Drosophila* seems to indicate that only the C_2B domain represents the necessary Ca^{2+} sensing domain required for synaptic vesicle fusion.

6 Systems Controlling Intracellular Ca^{2+} Concentration: Structural and Functional Properties

Owing to its function as an intracellular second messenger, the ionized Ca^{2+} has

to be kept in a narrow concentration range in the resting cell (i.e. 100–300 nM). On the other hand, as indicated before, the free Ca^{2+} concentration in the extracellular milieu is 2 to 5 mM. This results in a very steep concentration gradient across the membrane, and thus small changes in the free Ca^{2+} concentration can influence the different signal transduction pathways. Therefore, a number of different transmembrane Ca^{2+} transporting systems participate in controlling the free Ca^{2+} concentration in the cell. Most of these systems are either located in the plasma membrane (Ca^{2+} channel, ATP-dependent transporting system, Na^{+}/Ca^{2+} exchanger), in the sarco (endo)plasmic reticular system (ATPase, Ca^{2+}-release channel), or in mitochondria (an electrophoretic uptake system, a Na^{+}-dependent Ca^{2+} exchanger).

6.1 Calcium Transport Systems of the Plasma Membrane

6.1.1 The Calcium Channel

Transient changes in the intracellular free Ca^{2+} can be due to calcium deriving either from intracellular stores (see below) or from the extracellular fluid by passing through specifically regulated (i.e. gated) channels in the plasma membrane down their electrochemical gradient. Electrophysiological and pharmacological properties have been used to characterize different subtypes of the calcium channels. To date, six different types of channels have been identified: L, N, T, P, Q, and R. On the basis of their electrophysiological properties, using the well-established patch-clamp technique, it can be shown that these channels differ by their opening kinetics and their conductance:

1. L-type: *long-lasting* inward current and strong conductance (7–8 pS at 0.1 M Ca^{2+}) antagonist: dihydropyridines
2. T-type: *transient* inward current and a conductance of 5 to 10 pS at 0.1 M Ca^{2+}
3. N-type: originally defined as *neither* L-*nor* T-type channel (mainly found in *neurons*) with a characteristic activation by strong depolarization and intermediate conductance (11–15 pS at 0.1 M Ca^{2+}). Insensitive to dihydropyridines, but blocked by ω-conotoxin-GVIA
4. P-type: high-voltage activated channel, mainly found in cerebellar *Purkinje* cells, blocked by ω-Agatoxin-IVA but not by ω-conotoxin-GVIA

Recently, two other types of channels have been identified in Purkinje cells, Q-type and R-type channels. Q-type channels are less sensitive to ω-Agatoxin-IVA, whereas R-type channels are insensitive to ω-Agatoxin-IVA and ω-conotoxin-GVIA but sensitive to Ni^{2+}. All these channels are characterized by their difference in voltage dependence and their response to pharmaca. A different type of classification depending on the mechanism by which the transition between the ''open'' and ''closed'' conformations are regulated distinguishes between

1. voltage-operated channels (VOC) in which the gating depends on voltage as described above
2. receptor-operated channels (ROC) in which gating depends on ligand binding
3. store-operated channels (SOC) in which activation depends on the depletion of Ca^{2+} stores of the endoplasmic reticulum (ER) through a mechanism known as capacitative calcium entry (CCE).

Structurally, all VOC-type channels are complexes of four or five subunits ($\alpha 1$, $\alpha 2$, β, γ, and δ) forming large macromolecular complexes. The best-characterized examples are the **L**-type channels. The representative from skeletal muscle is composed of two high molecular weight components, $\alpha 1$ and $\alpha 2$, plus three smaller subunits β, γ, and δ. The channel protein represents a multigene family. To date, 10 distinct genes for the $\alpha 1$-subunit and three different ones for the β-subunit have been identified in mammals. The $\alpha 1$-subunit reveals some properties characteristic of voltage-gated channels. It is composed of four homologous repeated units containing six transmembrane regions and contains the conduction pore, the voltage sensor, and sites for gating and for channel regulation, for example, by protein kinases, by toxins, and by drugs. Dihydropyridines (e.g. nifedipine), phenylalkylamines (e.g. verapamil), and benzothiazepines (e.g. diltiazem) bind to three allosterically coupled binding sites on the $\alpha 1$-subunit. A physiologically important means of regulating these channels is provided by cAMP-dependent (PKA) phosphorylation increasing the opening probability of the channels. In reconstituted systems, it was shown that the $\alpha 1$- and β-subunits could be phosphorylated by PKA in a stoichiometric manner.

Three different kinds of **r**eceptor-**o**perated Ca^{2+} **c**hannels (ROC) have been identified. They are activated by L-glutamate and are named after the different agonists binding to these receptors as kainate (KA), α-amino-3-hydroxy-5-methyl-4-isoxazole proprionate (AMPA), or as N-methyl-D-aspartate (NMDA) receptors. They are located in the postsynaptic membrane. Most channels formed by KA and AMPA receptors are primarily permeable to Na^+ or K^+, but some of the AMPA receptors are also permeable to Ca^{2+}, whereas the NMDA receptors are permeable to Na^+ and Ca^{2+}. Several genes have been identified characterizing the different types of glutamate receptors. The mass of the different receptors ranges from 95 to 165 kDa.

In neuroendocrine cells, activation of an inward Ca^{2+} current occurs through channels known as store-operated Ca^{2+} channels (SOC). These channels have not been characterized in detail on the protein level, but they are homologous to the transient receptor potential (*trp* or *trp*-like) gene products of *Drosophila*. The mechanism by which these intracellular stores, probably derived from the endoplasmic reticulum, communicate their Ca^{2+} level to the plasma membrane in the form of a channel-opening signal is still under debate. The process, termed *capacitative calcium entry* (CCE) mediates smaller Ca^{2+} influx than the voltage-gated channels. Two hypotheses for the mechanism of CCE are discussed: one favors the liberation of a small chemical factor inducing the opening of the CCE channel, the other proposes some form of physical interaction between the ER and the plasma membrane CCE to trigger the opening.

6.1.2 The Ca^{2+} Pump

The Ca^{2+} pump of plasma membranes (PMCA) is important for the fine-tuning of the intracellular free Ca^{2+} concentration. It belongs to the P-type ion-motive ATPases like its counterpart from the endo (sarco)plasmic reticulum, the SERCA pump; that is, it forms an aspartylphosphate intermediate to transport Ca^{2+} against its concentration gradient across the plasma membrane on the expense of ATP. It is a protein of low abundance (e.g. 0.1% of the total membrane

proteins of the human erythrocytes), but it is ubiquitous in the plasma membranes of all cells. Calmodulin (CaM) activates the PMCA by direct interaction, thereby lowering the K_M for Ca^{2+} by one order of magnitude and increasing the V_{Max} two- to threefold; that is, as a result, the Ca^{2+} affinity and its transport rate are increased. This calcium-dependent affinity of the Ca^{2+} pump to CaM was also exploited to isolate the enzyme in pure form from detergent-solubilized erythrocyte membranes by applying calmodulin affinity chromatography. Next to the stimulation by CaM, the plasma membrane Ca^{2+} pump can also be activated by alternative treatments, that is, by acidic phospholipids, fatty acids, phosphorylation by different protein kinases (PKA or PKC, see below), oligomerization, or controlled proteolytic treatment. The latter procedure helped identify a number of functional domains of the enzyme (see Fig. 4). A significant difference in the properties between PMCA and the SERCA pump concerns the Ca^{2+}/ATP stoichiometry, which is 1 for PMCA but 2 for SERCA. In this respect, it is of interest that most polar residues that have been predicted (and confirmed through the structure) as participating in Ca^{2+} binding and transport through the

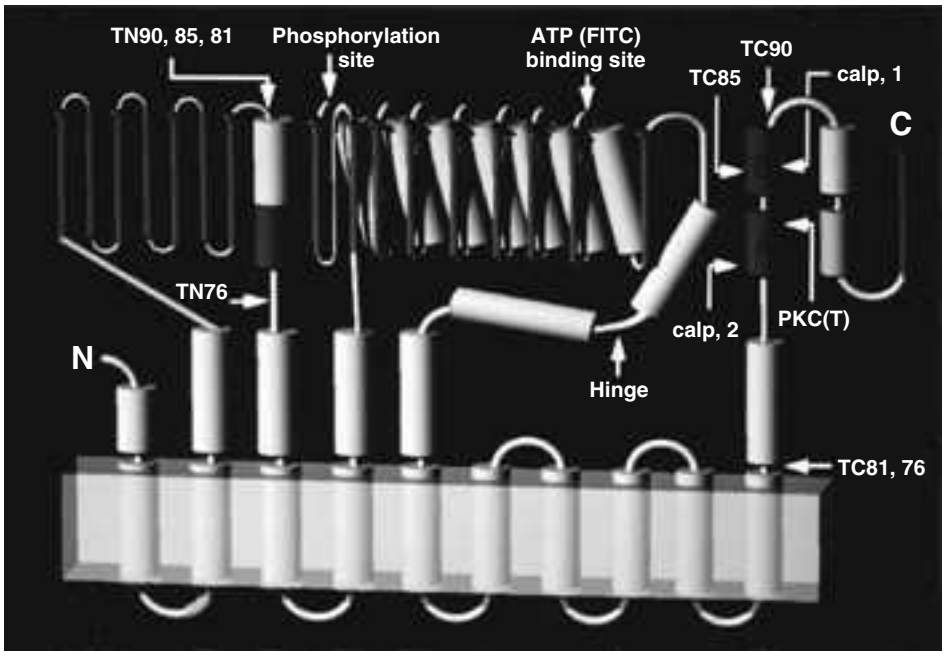

Fig. 4 Model of the topography of the plasma membrane Ca pump, illustrating the arrangement of the different functional domains assigned according to the primary structure of the enzyme and on the basis of secondary structure predictions. (A similar model of the SERCA pump was recently validated by solving the crystal structure, see text). The figure also includes different proteolytic cleavage sites (TN, TC), producing a number of enzymatically active fragments of different size (not discussed in the text); calp, calpain cleavage sites; PKC(T), threonine phosphorylatable by protein kinase C. (Reprinted with permission from Carafoli, 1992, *J. Biol. Chem.* **267**, 2115–2118.)

membrane within the SERCA pump (see below) have also been conserved in the PMCA pump. Consistent with the idea that the two pumps differ in the stoichiometry of Ca^{2+}/ATP was the finding that mutating Met882 of PMCA (M6) that corresponds to Thr799 (M6) in SERCA, and is known to be part of Ca^{2+} site II, had no influence on the activity of the PMCA pump. However, replacing Ala854 in PMCA (homologous to Glu771 in SERCA in M5) by a charged residue made the PMCA pump more similar to the SERCA pump with respect to the Ca^{2+}/ATP stoichiometry.

As typical for the P-type ion pumps, the Ca^{2+} pump of plasma membranes consists of a single polypeptide (ca. 1200 amino acids ≅135 kDa, depending on the isoform) spanning the membrane an even number of times (see Fig. 4); that is, the N- and the C-terminus are located on the same side of the membrane. This model of the PMCA pump gained validity owing to the recently solved structures of the Ca^{2+}-bound and the Ca^{2+}-free forms of the SERCA pump by Toyoshima et al., as will be discussed below. As demonstrated by this model, most of the pump mass protrudes into the cytosol with very short loops connecting the proposed transmembrane domains on the extracellular side. The cytosolic part of the enzyme can be divided into three different units.

1. Transduction or actuator (A) domain: It comprises the part of the pump between transmembrane domain 2 and 3, and, according to the structure of the SERCA pump, it should also contain the N-terminal sequence upstream of transmembrane domain 1. It is proposed to couple ATP hydrolysis to ion transport as in other ion pumps. An interesting part of this domain is the phospholipid binding domain that is unique to the plasma membrane Ca^{2+} pump as compared to other ion pumps, and that might play a role in specific tissue expression of isoforms since it was identified as one of the two alternative splicing zones of this protein (see below).

2. Catalytic domain: This unit spans the cytosolic part between the fourth and the fifth transmembrane domain (see Fig. 4) and, in analogy to the SERCA pump, contains the phosphorylation (P) and the nucleotide binding (N) domains. The P-domain contains the aspartyl phosphate site, the N-domain the ATP binding site, and the so-called ''hinge'' region, a highly conserved amino acid sequence among ion-pumping ATPases, which is involved in bringing the phosphorylation site near to the bound ATP. The catalytic unit further contains a receptor for the ''autoinhibitory'' calmodulin binding domain, a property that seems to be typical of CaM-dependent enzymes, and which differs PMCA from SERCA. This receptor is composed of two contact sites as identified by cross-linking experiments, one located between the P- and the N-domain, the other N-terminal to the phospholipid binding domain, thereby ''bridging'' the transduction and the catalytic domain and thus limiting the access of the substrate Ca^{2+} to the enzyme.

3. Regulatory domain: The sequence protruding into the cytosol after the last transmembrane domain until the C-terminus comprises several sites important for the regulation of the Ca^{2+} pump: the CaM binding domain and consensus sequences of two protein kinases, PKA and PKC (see Fig. 4). The PKA site is located C-terminal to the CaM binding domain, whereas the

PKC site is located within the CaM binding domain, and phosphorylation of this site can be prevented by the presence of CaM.

To date, four different genes of the PMCA pump have been identified in mammalian species. Additional variability of this multigene family is produced by alternative splicing within the phospholipid and the calmodulin binding domains. Splicing could give rise to differences in tissue-specific expression as well as to differences in affinity to calmodulin, for example, as documented for PMCA2, which has the highest affinity for calmodulin of all the isoforms studied to date. Four genes have been localized on human chromosomes: PMCA1 on chromosome 12, PMCA2 on chromosome 3, PMCA3 on chromosome X, and PMCA 4 on chromosome 1. PMCA1 and 4 are ubiquitously distributed, whereas PMCA2 and 3 are much more restricted in their tissue distribution, that is, the latter two are mainly found in the brain.

6.1.3 Na^+/Ca^{2+} Exchanger

Next to the Ca^{2+} pump, there also exists a Na^+-dependent Ca^{2+} exchanger in the plasma membranes of many cells, especially in excitable tissues. This Na^+/Ca^{2+} exchanger has a lower affinity for Ca^{2+} compared to the Ca^{2+} pump, but a much higher transport capacity. It is an electrogenic system; that is, it transports three Na^+ for one Ca^{2+}, the direction of the transport depending on the ionic transmembrane gradients or the transmembrane electrical potential, that is, the exchanger can operate fully reversible. Three homologous exchanger gene products (*NCX1, 2, 3*) have been identified; they are differently expressed in the heart, the brain, and the kidney. Hydropathy analysis has predicted 9 to 11 transmembrane domains, depending on the model, with the consequence that N- and C-terminus are located on opposite sides of the membrane. The size of the protein is between 110 and 120 kDa. Expression of the different gene products is controlled by tissue-specific promoters; some can be modulated by Ca^{2+}, for example, expression of *NCX2* in neurons is under the control of calcineurin, the CaM-dependent phosphatase.

6.2 Ca^{2+} Transport Systems of the Reticulum

Next to the Ca^{2+} transporting systems located in the plasma membrane, there are also intracellular organelles involved in controlling the free Ca^{2+} ion concentration of the cell. The reticular systems have best been studied in skeletal, smooth, and cardiac muscle cells, that is, the sarcoplasmic reticulum, but also the related endoplasmic reticulum of other cells gained importance owing to the knowledge that the Ca^{2+} content of these stores can be released into the cytosol by inositol-1,4,5-phosphate (IP_3). This latter second messenger links plasma membrane receptor activation response to extracellular hormonal stimuli to Ca^{2+} mobilization from intracellular stores.

6.2.1 The IP_3 Receptor

IP_3 is produced by receptor-activated phospholipase C–dependent hydrolysis of phosphatidyl inositol diphosphate (PIP_2). Subsequently, IP_3 binds to a specific receptor located in the membranes of the ER, thereby releasing calcium into the cytosol through the Ca^{2+}-ion channel of the receptor. The IP_3 receptor, which is highly concentrated in the Purkinje cells of the cerebellum, has been identified

and purified to a single protein band corresponding to 260 kDa. However, the molecular weight of the native receptor is about 1 million Da, indicating that the receptor is a homotetramer.

IP_3 receptors can be phosphorylated by different kinases (PKA, PKC, CaM kinase II) in a stoichiometric manner, resulting in a reduced potency of IP_3 in releasing Ca^{2+} from the ER. Thus, regulation of the IP_3-induced Ca^{2+} release by phosphorylation of the receptor is a means of ''communication'' between different second messenger systems.

Cloning and sequencing of cDNA of the IP_3 receptor was first accomplished by Mikoshiba et al. IP_3 receptors from different species revealed a high degree of conservation and homology. The sequence further demonstrates a high degree of similarity to the ryanodine-binding Ca^{2+}-release channel of the SR with which it also shares functional similarity. Like the latter, the main protein mass protrudes into the cytosol with both the N- and the C-terminus being on the cytosolic side, resulting in an even number of transmembrane domains. The IP_3 binding site lies within the first 400 amino acids from the N-terminus, whereas the putative Ca^{2+} channel is located within the transmembrane regions of the C-terminal end, indicating a large spatial distance for coupling the IP_3 binding to the Ca^{2+} release through a conformational change.

6.2.2 The Ca^{2+}-release Channel

The sarcoplasmic reticulum (SR) of striated muscles is an important feature involved in the regulation of excitation–contraction coupling of muscles. It is composed basically of two elements: (1) the longitudinal tubules surrounding the myofibrils and (2) the terminal cisternae. The latter are in contact with the transverse tubular system (T-tubules), a periodic inflection from the plasma membrane (the sarcolemma) forming a junctional gap that is crossed by periodic ''feetlike'' structures. These structures, originally described as the ryanodine receptor (RyR), have been identified as the calcium-release channel of the SR, forming tetramers as functional units. The amino acid sequence of the monomer, consisting of more than 5000 amino acids, has been deduced from the cDNA by the group of Numa. An unusual feature of these proteins is the existence of only four potential transmembrane domains right at the C-terminal end indicating that more than 90% of the protein protrudes into the cytosol. This, on the other hand, would provide an attractive morphological explanation for the existence of these ''feetlike'' structures spanning the 150-Å gap between the SR and the T-tubules and, furthermore, would provide the possibility for a physical interaction between the Ca^{2+}-release channel of the SR and the voltage-dependent Ca^{2+} channel concentrated in the T-tubules and identified as dihydropyridine receptors or L-type Ca^{2+} channels (see above). These features would provide a rational explanation for a direct triggering of Ca^{2+} release by these Ca^{2+} channels located in the T-tubules.

Three distinct RyRs have been identified. RyR1 is predominantly expressed in skeletal muscles, RyR2 in heart and brain, and RyR3 in some regions of the brain (e.g. hippocampus, diencephalon). Even if RyR was originally described as the Ca^{2+}-release channel of the sarcoplasmic reticulum, it is now well known that RyR is also widely distributed in nonmuscle cells. In these cells, cyclic ADP-ribose appears to be the natural second messenger for inducing Ca^{2+} release from the channel.

6.2.3 The Ca^{2+} Pump

The principle protein component of the sarcoplasmic reticulum (SR) is the Ca^{2+} pump (SERCA) transporting Ca^{2+} from the cytosol into the lumen of the reticulum against the concentration gradient across the membrane. This protein can represent as much as 90% of the membrane protein (in SR of skeletal muscles), but even in the SR of heart cells, it can still make up to 50%. Similar to the plasma membrane Ca^{2+} pump, the protein consists of a single polypeptide chain of about 100 kDa. The predicted secondary structure and membrane topography as suggested by MacLennan, Green et al. was impressively confirmed by the recently solved structures of the Ca^{2+}-bound and Ca^{2+}-free forms (the latter in the presence of the SERCA-specific inhibitor thapsigargin) by Toyoshima et al. (see Fig. 5). The properties of the SR Ca^{2+} pump can be summarized as follows:

1. The hydrophobic portion is made up of 10 transmembrane helices as predicted.
2. Transmembrane helix M5 continues into the cytosol (60 Å total length) coupling the membrane portion to the cytosolic domains.
3. The major protein mass protrudes into the cytosol divided into the actuator (A), phosphorylation (P), and the nucleotide binding (N) domains, the latter being inserted within the P-domain (see Fig. 5). The P- and N-domains, connecting transmembrane helices 4 and 5, provide the catalytic center of the enzyme, with the conserved aspartyl residue (D351) being phosphorylated during the reaction cycle.
4. Two Ca^{2+} binding sites could be identified within the transmembrane part of the SERCA pump comprising polar residues of helices M4, M5, M6, and M8. This is a necessary prerequisite for the stoichiometry of two calcium ions being pumped/ATP during one reaction cycle, and confirms strongly those residues participating in the transport of calcium as identified by mutational experiments.
5. Large-scale movements of the A-, P-, and N-domains occur during the reaction cycle as suggested by comparing the Ca^{2+}-free with the Ca^{2+}-bound structure. These domain movements are coupled to changes in tilt and position of helices M1 to M6.
6. One of the significant differences between the two Ca^{2+} pumps of plasma and reticular membranes concerns the C-terminal part. In contrast to the plasma membrane Ca^{2+} pump, the SR protein does *not* directly interact with calmodulin; that is, it lacks the corresponding regulatory domain, but some isoforms can be regulated by a CaM kinase through phosphorylation of phospholamban (PLN) (see below).
7. The SR Ca^{2+} pump of cardiac or smooth muscles, that is, of slow twitch muscles, is regulated by a highly hydrophobic, phosphorylatable protein called *phospholamban* (PLN), composed of an N- and a C-terminal helix connected by a short, flexible hinge region. PLN interacts with the SERCA pump within the transmembrane region as well as with a small loop of the P-domain. PLN can be phosphorylated by different kinases, that is, by PKA and by a CaM-dependent kinase, thereby leading to a significant stimulation (up to fivefold) of the SR Ca^{2+} pump. Thus, the unphosphorylated form of phospholamban can be viewed as an endogenous inhibitor of the SR Ca^{2+} pump similar to the CaM binding domain of the Ca^{2+} pump of plasma

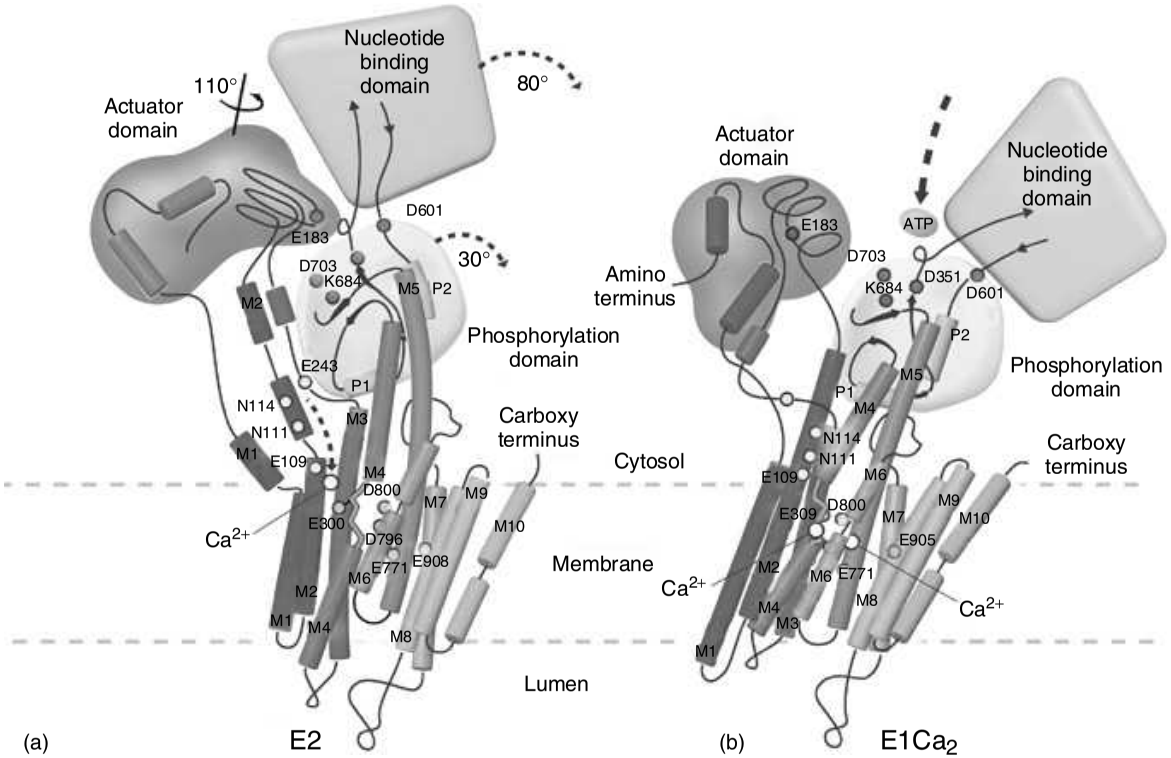

Fig. 5 Structures of the SERCA pump in (a) the Ca^{2+}-free (thapsigargin-bound) form and (b) the Ca^{2+}-bound form. The three cytosolic domains are indicated as A (actuator), P (phosphorylation), and N (nucleotide binding) domains. The P-domain (with N inserted) connects transmembrane helices M4 and M5. Within the P-domain, Asp351, which is phosphorylated during the reaction cycle, is also indicated. A number of residues important for the catalytic center or the Ca^{2+} binding sites within the membrane are shown (Reprinted with permission from Green & MacLennan, 2002, *Nature* **418**, 598–599).

membranes, which is an autoinhibitory domain.

Three different genes have been identified to date to encode the SERCA pump. SERCA1 is mainly found in the fast-twitch skeletal muscle, whereas SERCA2 is the major form of cardiac, smooth, and nonmuscle tissues. SERCA3 has been cloned from a kidney library and is prominently present in platelets. For SERCA1 and 2, several spliced isoforms also have been described.

6.3 The Mitochondrial Calcium Transporting Systems

Like the reticular systems, mitochondria also provide intracellular calcium-transporting systems sequestering Ca^{2+} by means of energy-dependent processes. The mitochondrial calcium transporters, that is, a Ca^{2+} uniporter and a Na^{+}/Ca^{2+} exchanger, were thought, for a long time, to play a minor role in the constant regulation of the cytosolic Ca^{2+} concentration since the mitochondrial Ca^{2+} uptake rate is about 10-fold slower than that of the SR, and the K_M value for the transporter is 10-fold higher than that of the reticular systems. Using Ca^{2+}-specific indicators targeted to different organelles, it became clear that mitochondria were very important for sensing Ca^{2+} changes in "microdomains" of the cell, rather than in the bulk cytosol; that is, increase of cytosolic Ca^{2+} induced by IP_3 was paralleled by a rapid increase of mitochondrial Ca^{2+}. It soon became clear that the activation of mitochondrial Ca^{2+} uptake was the result of the proximity of the mitochondria and the ER, and the release of large amounts of Ca^{2+} by the latter could create microdomains of local high Ca^{2+} concentrations, sufficient to activate the low-affinity mitochondrial Ca^{2+} uniporter. In spite of concentrated studies, however, the molecular nature of this mitochondrial Ca^{2+} transporting system could not be identified to date.

6.4 Calcium in the Nucleus

The nucleus is separated from the cytosol by the nuclear envelope consisting of two concentric membranes, of which the outer membrane is continuous with the ER. The nuclear envelope is not a completely closed system but is interrupted by the nuclear pores, large multicomponent protein complexes that regulate the transport into and out of the nucleus. Whether Ca^{2+} can freely diffuse through these pores like most small molecules or whether it is gated is still controversial, but it is clear that there are important Ca^{2+}-dependent processes occurring in the nucleus, including Ca^{2+}-dependent gene expression. A key factor of Ca^{2+}-dependent gene expression (including a number of Ca^{2+} transporting systems) is the transcription factor CREB, originally identified as the protein recognizing cAMP-responsive elements. Thus, CREB can be activated by phosphorylation of a serine residue, Ser133, either by cAMP-dependent PKA or by a CaM-dependent protein kinase, CaMKII or IV. In this respect, a recent finding is of particular interest, showing that the mode of entry of Ca^{2+} into cells, that is, via the voltage-dependent calcium L-channel or through other means, specifies the response to Ca^{2+}-dependent gene transcription.

Another pathway of Ca^{2+}-dependent gene transcription recently attracted much attention, that is, the transcription factor NFAT that has originally been described as being important in T cells and that is under

the control of the CaM-dependent phosphatase calcineurin. Similar findings have recently been reported for neurons, where calcineurin regulates the gene expression of some of the Ca^{2+} transporters. This is especially true for the cerebellum, where calcineurin mediates the rapid transcriptional downregulation of specific isoforms of the PMCA pumps and of the NCXs.

Ca^{2+} can also regulate transcription directly through the recently identified transcription factor DREAM (**d**ownstream **r**egulatory **e**lement **a**ntagonist **m**odulator), which is an EF-hand-type protein. Ca^{2+}-free DREAM binds to the regulatory element DRE, thereby silencing the gene that is released owing to the binding of Ca^{2+} to DREAM.

7
Role of Calcium in Specialized Tissues

7.1
Calcium and Fertilization

Interaction of sperm with the egg upon fertilization results in a sharp increase in Ca^{2+} concentration, thereby depolarizing the plasma membrane. Subsequently, phospholipase C is activated and phosphoinositide lipid turnover is induced leading to IP_3 generation, a prerequisite to release Ca^{2+} from intracellular stores. Also, cyclic ADP-ribose/RyR channels and NAADP-sensitive Ca^{2+} stores contribute to Ca^{2+} mobilization. Several mechanisms are discussed to be responsible for the elevation of Ca^{2+} during fertilization; the most likely candidate is of proteinaceous nature. Nevertheless, irrespective of the mechanism, the immediate consequence of Ca^{2+} rise is the exocytosis of cortical granules responsible for the elevation of the fertilization envelope to prevent polyspermy.

7.2
Calcium in Calcifying Tissues

Bone is formed by osteoblasts of mesenchymal origin and resorbed by osteoclasts of hematopoietic stem cell origin. In this highly integrated process, it is important to maintain a balance between the formation and resorption of bone. If one part dominates over the other, leading either to osteopetrosis, that is, increase of bone formation, or to osteoporosis, that is, increase of bone resorption, one of the consequences is the imbalance of the calcium homeostasis. Therefore, it is important for a variety of cells to sense changes in the extracellular Ca^{2+} levels to be able to modify their functions accordingly. The existence of such calcium sensors has first been demonstrated for the parafollicular cell of the thyroid gland (C-cell) and for the parathyroid cell, which through the secretion of parathyroid hormone regulate the level of serum calcium, that is, responding to changes in PTH secretion inversely related to the ambient ionized calcium concentration. These cells can recognize small changes in the extracellular Ca^{2+} concentration through a "Ca^{2+} receptor," presumably a cell-surface receptor protein, which in the case of cytotrophoblast cells of the human placenta has been identified as a protein of 500 kDa. In the case of osteoclasts that can locally be exposed up to 30 mM Ca^{2+} during bone resorption, increase in extracellular Ca^{2+} concentration leads to an increase in intracellular Ca^{2+} resulting mainly from influx of extracellular Ca^{2+} through voltage-insensitive channels. This in turn leads to a modification of the cytoskeletal arrangement of these highly polarized cells, to a reduction of specific adhesion structures responsible for the attachment to bone, and, finally, to an

inhibition of bone resorption accompanied by a reduction in the secretion of resorptive enzymes.

7.3 The Role of Calcium in Plants

Most Ca^{2+} dependent signal transduction pathways as described for animal cells are also true for plant cells. So it is not surprising that most systems described before controlling calcium homeostasis found their counterparts in plants also. Nevertheless, there are some peculiar Ca^{2+}-dependent processes or properties, only found in plants, which should be described in more detail.

7.3.1 Touch Genes

Plants show some specific reactions that seem to be calcium-dependent; that is, they sense and actively respond to many environmental stimuli such as rain, wind, gravity, changes in osmotic conditions, and touch. The latter is demonstrated very impressively by the Venus fly trap (*Dionaea muscipula*) using a sensitive touch response to catch preys, or by the *Mimosa pudica* closing the leaflets upon touch stimuli. It was discovered by Braam and Davies that the plant *Arabidopsis* demonstrated a rapid and strong induction of gene expression following touch stimulation. Several of these genes revealed either virtual identity or close relationship to calmodulin, indicating that these gene products may play a central role in Ca^{2+}-dependent signal transduction pathways involved in touch response. The response is relatively fast; for example, all of the responding genes showed up to 100-fold increased expression after 10 min, but maximal expression varied for the different genes. Furthermore, these genes not only demonstrated a time-dependent but also a dose-dependent response to touch stimuli; that is, the level of transcripts of the touch genes was proportional to the strength of the stimuli. These findings indicated that there is an immediate, but transient, requirement for Ca^{2+} binding proteins following mechanical stimulation, resulting in growth inhibition. It is possible that these proteins act as Ca^{2+}-dependent modulators of target enzymes, but other explanations are also possible such as involvement in the regulation of cellular Ca^{2+} homeostasis or changing microtubular arrangements. The latter is particularly attractive since this activity could influence the orientation of the axes of cell division and elongation as a consequence of mechanical stimulation.

7.3.2 Calmodulin-like Domain Protein Kinase (CDPK)

In plants, a new class of calcium-dependent kinases has been described. These enzymes require micromolar Ca^{2+} concentrations for activity, but they do not seem to need the presence of calcium effector molecules such as calmodulin, phosphatidylserine, or diacylglycerol. It could be demonstrated that they bind Ca^{2+} directly through a regulatory domain on the same polypeptide chain containing the catalytic domain. Cloning of the corresponding cDNA encoding a calmodulin-like domain protein kinase (CDPK) revealed characteristic regions of serine/threonine kinases. In addition, the regulatory region contains a domain with a high degree of homology to calmodulin including four Ca^{2+} binding sites of the EF-hand-type family. Thus, the CDPK family can be distinguished from other calcium-regulated protein kinases by fusion of a regulatory, calcium binding, calmodulin-like domain to a protein kinase catalytic domain. Investigation of the substrate specificity of this

kinase revealed an overlapping with CaM kinase II and protein kinase C. Together with the ubiquitous distribution of CDPK in plants, this observation suggests a multifunctional kinase property for this enzyme, but specific endogenous substrates still have to be identified to characterize the role of CDPK in calcium signal transduction pathways in plants.

8 Calcium and Disease

Sustained raise of cellular Ca^{2+} into the micromolar range leads to deleterious effects upon Ca^{2+} signaling, which could eventually lead to cell death. Mutations of the intracellular Ca^{2+}-dependent protease, calpain, the activity of which normally is tightly controlled – like disruption of the gene responsible for a muscle isoform – cause muscular dystrophy type 2A, whereas mutations of another isoform lacking the C-terminal Ca^{2+} binding domain favor the onset of type 2 diabetes.

As indicated before, bone formation and bone resorption is a highly integrated process that, in cases of misbalance, leads to severe diseases (e.g. osteopetrosis, osteoporosis, Paget's disease) and thereby influences calcium homeostasis. The reason for these malfunctions can be manifold and will not be discussed here, but recently two examples became known in which disturbance of calcium homeostasis could be traced to mutations of single proteins involved in Ca^{2+} regulation.

Malignant hyperthermia is manifested in humans and swine as an acute hyperthermic reaction accompanied by skeletal muscle contracture and high fever, indicating a lack of regulation of Ca^{2+} within muscle cells. This could be due to either an enhanced or chronic release of Ca^{2+} into the cell or due to a defective reuptake of Ca^{2+}. Detailed studies by MacLennan and his laboratory implicated a defect in the Ca^{2+} release mechanism that could be traced to a number of mutations within the gene of the ryanodine-sensitive Ca^{2+}-release channel in the sarcoplasmic reticulum of skeletal muscle. To date, more than 20 different mutations linked to this defect have been described in the *RyR1* gene.

Defects in the genes of the two brain-specific isoforms of the plasma membrane Ca^{2+} pump, PMCA2 and 3, have also been described. Of special note is PMCA2 that is abundant in the outer hair cells of the organ of Corti. Recent findings in mice with hearing defects localized genetic mutations within PMCA2, which could be used as a model for investigating hearing defects in humans.

Vitamin D–resistant rickets is an autosomal recessive disorder resulting from an inability to regulate Ca^{2+}, which leads to bone demineralization, loss of hair, and increased levels of the active vitamin D metabolite 1,25 $(OH)_2D_3$. As shown by Hughes et al., the reason for these defects lies in a number of inherited mutations of the vitamin D receptor, a member of the steroid/thyroid family of hormone-sensitive transcription factors. The mutations identified so far fall either into the DNA binding or into the hormone binding domain.

9 Conclusions

In summary, several general points can be made:

1. Calcium, as one of the oldest components of organisms, plays a central

role in biological systems, controlling a myriad of key cell processes. It can fulfill a static function, in stabilizing structures, or a dynamic function, participating in signal transduction pathways as a second messenger.

2. Calcium homeostasis in an organism is carefully controlled, involving a variety of systems in the skeleton, in the ECF, and inside cells. Depending on its function, calcium can be complexed in different forms: by hydroxyapatite in the skeleton; by acidic, low-affinity proteins in the ECF; by the high-affinity EF-hand proteins inside cells.
3. Extracellular and intracellular concentrations of calcium differ by several orders of magnitude. Therefore, cells are exposed to a steep Ca^{2+} gradient across the membranes, which makes it possible for even small changes in membrane permeability to lead to substantial changes in intracellular free Ca^{2+} concentration. Signals can be converted from an extracellular analog to an intracellular digital form. The control of cellular calcium is maintained by an elaborate system of channels, exchangers, and pumps located in the plasma membrane and in intracellular membranes.
4. The EF-hand proteins play a pivotal role in permitting Ca^{2+} to function as a second messenger. These proteins bind Ca^{2+} with high affinity, selectivity, and cooperativity, thereby permitting interaction with targets. More than 600 EF-hand proteins have been identified to date, which fulfill the different tasks of calcium-dependent mechanisms (e.g. glycogen metabolism, muscle contraction, excitation–secretion coupling, cell cycle control, gene expression, mineralization).
5. Solving the structure of several key components of calcium-controlled pathways helped understand their mechanism of action.

Keywords

Cancer
One of the most common human diseases.

Drug Design
The process of developing a new medicine.

Therapy
The administration to human subjects of a drug

p53
A tumour suppressor protein seen to be frequently mutated in cancer cells.

Cell Cycle
The process through which cells grow and divide.

Angiogenesis
The formation of new blood vessels.

Hsp90
A ubiquitously expressed protein that acts to protect cells from thermal stress.

Erb B
The epidermal growth factor receptor.

E2F
A key protein transcription regulating protein involved in cell cycle control.

The massive research efforts that have been applied to understanding the workings of the cancer cell have provided a wealth of detail on key mechanisms that become abnormal during tumorigenesis. Translating and exploiting this large body of cancer research information in the design and implementation of new drugs should yield better medicines for the cancer patient than those that are currently available. It is an implicit assumption in this objective that mechanism-based agents that target discrete abnormalities in tumor cells will provide improved treatments over conventional therapies. In this respect, we are beginning to witness emerging clinical efficacy in a new generation of cancer drugs designed to target key mechanisms in tumor cells.

1 Cancer Therapy

Cancer remains largely a clinically unmet disease. Statistics tell us that cancer affects one person in three, and in the Western world, it is the cause of about a quarter of all mortality. Worldwide, cancer is the second largest cause of death, and the World Health Organization estimates that by 2020, there will be 20 million new cancer patients each year. Cancer is not a single disease, as there are over 200 different types of diseases that fall into this category. However, four cancers dominate, namely, lung, breast, colon, and prostate, which account for over half of all new cases.

Most current cancer therapies employ one of three approaches, namely, surgery, radiotherapy, or chemotherapy. Surgery and radiotherapy are frequently used to treat localized primary tumors, but have limited application in disseminated disease in which the tumor is not localized, usually as a result of metastasis. Needless to say, disseminated disease is the cause of most cancer deaths. Current cancer chemotherapy is dominated by treatments that use cytotoxic agents or hormone-based therapy, for example, in breast and prostate cancer (Table 1).

Tab. 1 Examples of conventional cancer chemotherapeutic agents.

Drug	*Category*
Methotrexate	Antimetabolite
Taxol	Spindle modulator
Cyclophosphamide	Alkylating agent
Cisplatin	Platinum-DNA complexes
Doxorubicin	DNA intercalating/topoisomerase inhibitor

Furthermore, while advances have been made in all three approaches to treatment, the impact on mortality rates has been modest. As an example, lung cancer, the leading cause of cancer death worldwide, has a five-year survival rate of only 5%, which hardly differs from the survival that prevailed 30 years ago (www.cancerresearchuk.org). However, there are some notable improvements. Cures are achievable in certain childhood leukemias and testicular cancer, although of the six most common cancers, only breast cancer has a survival rate greater than 50%. Overall, conventional chemotherapy is relatively ineffective in many cancers.

This situation reflects the mechanism of action of most current cancer therapy regimes, which are dominated by cytotoxic chemotherapies (Table 1). In general, these chemotherapies target mechanisms employed by most dividing cells, rather than specific genetic abnormalities associated with tumor cells. Because of this, their normal healthy counterparts are affected almost as severely as the tumor cells, leading to the highly debilitating side effects seen with many therapies, such as myelosuppression, hair loss, and gastrointestinal toxicity. This problem, combined with the poor quality of life and diminishing effectiveness in the patient (usually because of the emergence of drug resistance), means that many late stage cancer treatments provide minimal survival advantage.

2 The New Era of Mechanism-based Drug Design

Because of the limited therapeutic value of many current treatments, major efforts are being applied toward identifying new cancer therapies that target

specific mechanisms in tumor cells, in the hope that this approach will yield drugs with increased specificity for cancer. Here, we review progress and provide a snapshot of this rapidly advancing field. Selected examples of mechanism-based drug design programs, which illustrate the guiding principles behind the new era of cancer drug development, are discussed. The success stories are clear; a situation we anticipate will be repeated in the continuing efforts to deliver tailored therapies into the cancer clinic.

3 Gleevec and CML

Gleevec (ST1571) provides a paradigm for a successfully developed, rationally designed, and mechanism-based therapy for the treatment of a specific cancer. In chronic myelogenous leukemia (CML), the consistent chromosomal abnormality, the Philadelphia (Ph) chromosome, is a translocation event between chromosome 9 and 22 that results in the bcr-*abl* fusion product derived from the juxtaposition of c-*abl* oncogene and breakpoint cluster region (bcr). bcr-*abl* is present in over 95% of CML patients and in about 5% of acute lymphoblastic leukemia (ALL) patients in whom it functions as a constitutively active tyrosine kinase that is essential for the oncogenic activity of the fusion protein (Fig. 1).

Originally, Gleevec was identified by high-throughput screening for compounds with kinase inhibitory activity, and was subsequently optimized using rational drug design procedures for activity against Abl tyrosine kinase in CML cells. A successful Phase I study indicated remarkable single agent activity during CML blast crisis (and Ph-positive ALL), although the responses did not appear to be long term. Nevertheless, the success in Phase I prompted further Phase II clinical analysis, followed by FDA approval.

The appearance of resistance to Gleevec was a surprising clinical outcome: the majority of CML patients that relapse after initial response have reactivated bcr-*abl* kinase. Molecular analysis indicated that in many cases resistant cells carry point mutations in the *abl* kinase gene that rendered the kinase less sensitive to STI571, for example, at a site that would be predicted to contact STI571 from the crystal structure. In another category of patients, relapse was correlated with amplification at the bcr-*abl* translocation. These results suggest that while rationally designed drugs like Gleevec may exhibit promising clinical efficacy, the appearance of resistance could be a significant problem.

Gleevec also inhibits the c-kit tyrosine kinase where activating mutations are found in gastrointestinal stromal tumors (GIST), a tumor frequently refractory to chemotherapy. While a range of other tumors express c-kit, the encouraging results of the Gleevec Phase I study on GIST suggest that its clinical application may be wider than initially anticipated, with the proviso that clinical resistance may also appear in other indications.

4 The ErbB Family

The epidermal growth factor (EGF) family of tyrosine kinase receptors (the ErbB receptors) play a crucial role in regulating proliferation. In tumor cells, a variety of mutagenic events give rise to increased ErbB activity, including gene amplification and mutations that alter protein stability.

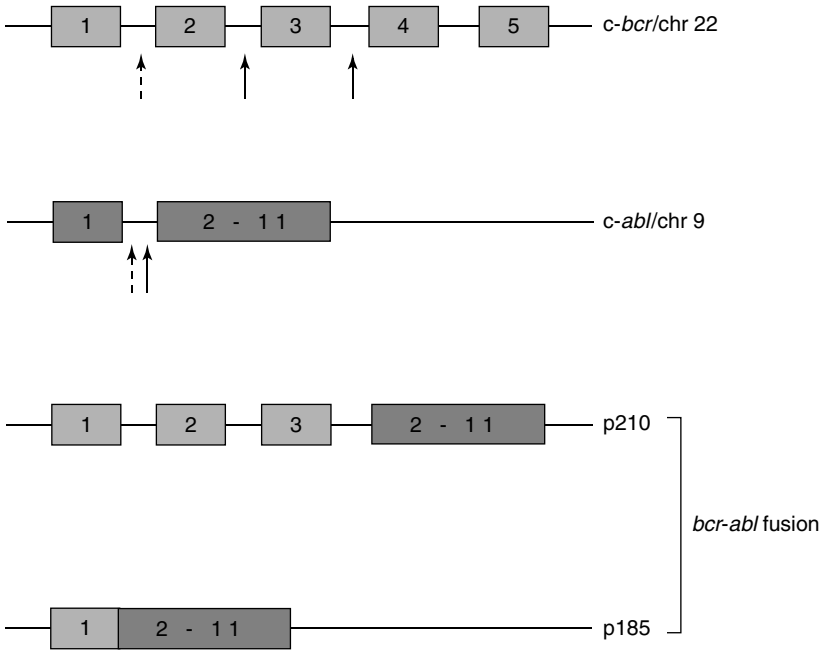

Fig. 1 Chromosomal breakpoints in chronic myelogenous leukemia (CML) and acute lymphoblastic leukemia (ALL). In CML and ALL, a breakpoint occurs between the first exon of c-*abl* on chromosome 9, translocating most of c-*abl* to c-*bcr* on chromosome 22. In CML, the translocations in c-*bcr* occur after exon 2 or 3, to yield the p210 fusion protein, and in Ph-positive ALL, they occur after exon 1 to create p185. The solid arrows indicate CML breakpoints and broken arrows indicate ALL breakpoints.

Both humanized monoclonal antibodies and small molecules have been developed against ErbB1 (also known as EGF receptor and HER1) and ErbB2 (also known as HER2 and Neu). Herceptin (trastuzumab) has received regulatory approval as a single agent for treatment of metastatic breast cancers expressing ErbB2, whereas other humanized antibodies against ErbB1 such as Cetuximab remain in clinical development.

Iressa (ZD1839) is an optimized small molecule ATP competitive antagonist of the ErbB1 tyrosine kinase, originally identified by high-throughput screening and subsequently shown to be active against breast cancer cells. Phase II clinical trials with Iressa demonstrated activity in nonsmall cell lung cancer (NSCLC), squamous cell carcinomas of the head and neck, and hormone refractory prostate cancer. Recently, Iressa was evaluated in a randomized Phase II study for activity in advanced NSCLC, where it was found that it did not provide improvement in survival when added to standard platinum-based chemotherapy.

A significant question regarding the clinical utility of mechanism-based drugs like Iressa relates to how they will be used in the clinical setting. A relevant administration schedule and, as mechanism-based drugs may be cytostatic, identifying an appropriate combination agent and patient population are likely to be critical determinants in reaching optimal clinical efficacy.

5
Manipulating p53 Tumor Suppressor Activity

As one of the most frequently mutated genes in human cancer, the p53 tumor suppressor protein has attracted great interest from drug discoverers. In normal cells, p53 acts as a stress-responsive transcription factor, becoming activated in response to, for example, ionizing radiation, ultraviolet light, and many cancer chemotherapeutic drugs. Once activated, p53 targets genes involved in limiting cellular proliferation, causing either cell cycle arrest or apoptosis (Fig. 2). Its frequent inactivation in cancer has led to many attempts to identify ways of reinstating p53 activity, or approaches that exploit the absence of p53 in tumor cells. However, though it is an intrinsically difficult task for a small molecule to reinstate wild-type activity in a mutant protein, the extensive number of distinct mutations (over 1700 different mutations have been reported) that can occur in the p53 gene provides an additional challenge to this approach.

Despite these significant obstacles, compounds have been identified that reinstate certain wild-type functions on mutant p53 protein. These compounds appear to stabilize p53 in a form that allows some properties of the p53 response to be retained. Relating to this general strategy is the identification of p53-binding peptides, which similarly stabilize mutant p53, providing further support for the idea that the ultimate goal of generating compounds that reinstate p53 activity may be achievable.

In another approach that exploits p53 activity, attempts have been made to generate compounds that block p53 activity. A potential therapeutic application for such inhibitors would be in reducing the level of p53-dependent toxicity in normal healthy tissues that occurs, for example, upon cancer therapy. Pifithrin α, which reduces p53 activity, was identified by high-throughput screening in a cell-based p53 screen. The

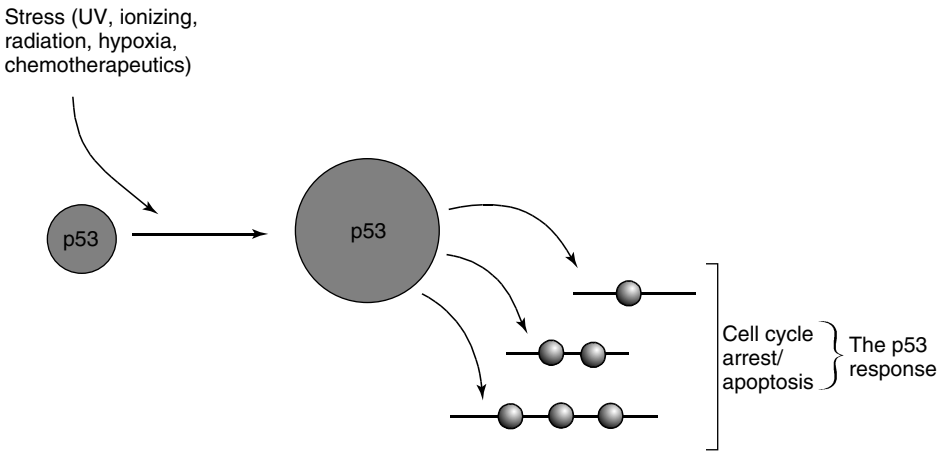

Fig. 2 The p53 response. In normal cells, p53 can be activated by different types of stress, and it then acts to transcriptionally induce target genes that cause cell cycle arrest and apoptosis. In tumor cells, the activity of p53 is lost through mutation in the p53 gene, or in upstream regulators that control p53 activity.

compound is active in mice where it reduces the side effects, such as hair loss and myelosuppression, of the widely used cancer cytotoxic agent doxorubicin.

Although the anticipated clinical utility of p53 inhibitor drugs would be in combination treatments to enhance the efficacy of a conventional cytotoxic, a shortcoming of this approach could lie in the potential mutagenic activity resulting from p53 inhibition. Developing a p53 inhibitor with a sufficiently short half-life may overcome such a concern.

6 Regulating the Cancer Cell Cycle: E2F and Cdks

Abnormal cellular growth and division is a hallmark of tumor cells. It is acquired through a multistep process involving the gradual transformation of a normal cell to a tumor cell, and it involves mutation of critical pathways that act to restrain proliferation, together with the activation of those that promote proliferation.

The retinoblastoma tumor suppressor protein (pRb) provides a perfect example of how a crucial point of growth control can become abnormal in tumor cells, and thereby contribute to tumor cell growth. An important function of pRb is in regulating cell cycle progression through G1 into S phase, particularly passage through the restriction point, where it influences the activity of the E2F family of transcription factors (Fig. 3). E2F coordinates the timely expression of a large body of genes required for cell cycle progression (including DNA synthesis, cyclins, and regulatory proteins), and it is the progressive phosphorylation of pRb that relieves its physical interaction with E2F, thereby enabling E2F to activate target genes (Fig. 3).

Tumor cells employ diverse mechanisms to overcome the tumor suppressor activity of pRb. The Rb gene is mutated in about 25% of human tumors, crippling pRb so that it is not able to bind to E2F. Alternatively, aberrant levels of upstream regulators of pRb, like cyclin D-dependent kinase, occur which leads to the constitutive phosphorylation of pRb and release of E2F. Because of the high frequency of abnormal pRb control, it is believed that deregulation of the pRb/E2F pathway is essential in achieving the transformed state.

In this respect, E2F is an obvious target for therapeutic intervention, and several approaches have been made toward its validation as a cancer target. That E2F plays a crucial role in the cell cycle is supported by E2F knockout cells, in which inactivation of E2F-1, -2 and -3 causes cell cycle arrest. Furthermore, administering short oligonucleotides containing the E2F DNA binding site to sequestor E2F activity away from cellular target genes, the so-called *decoy* approach, prevents cellular proliferation, and short peptides that block E2F function by inhibiting dimerization (with its essential partner protein DP-1) or its interaction with DNA cause apoptosis in tumor cells. Furthermore, a small molecule that is believed to act by modulating the E2F pathway has entered Phase I clinical studies.

Other regulatory factors involved in control of the pRb/E2F pathway, including cyclin-dependent kinases (Cdk) have also attracted considerable attention as a drug target. Though most members of the Cdk family control cell cycle transitions such as cyclin D/Cdk4 and cyclin E/Cdk2 (Fig. 3), other members have been assigned much more specific roles, like cyclinT1/Cdk9, which regulates targets including RNA

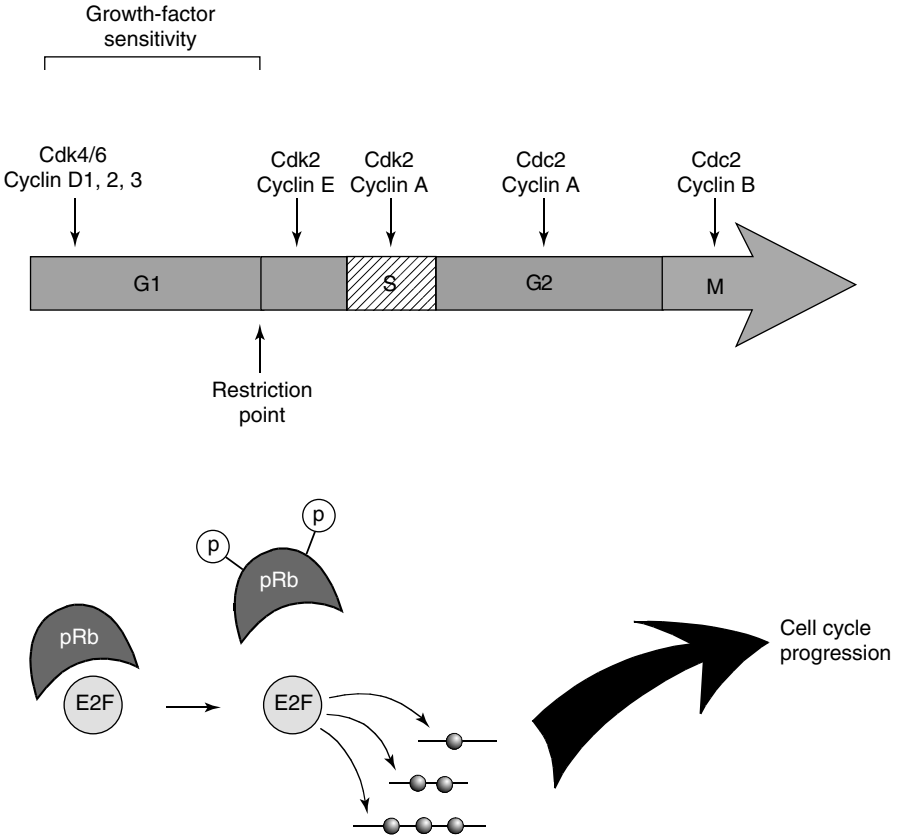

Fig. 3 Regulation of the cell cycle. The four phases of the cell cycle is indicated, together with the nature and the timing of the cyclin-Cdk complexes involved in cell cycle progression. The Restriction point, positioned in G1(R), is the point at which cells become committed to cell cycle progression and no longer require growth factors. The regulation of E2F activity, which controls the early cell cycle, is indicated underneath. In normal cells, the pRb binds to E2F to inactivate E2F activity. As pRb becomes phosphorylated (indicated by p) by Cdk complexes, E2F is released leading to the activation of target genes required for cell cycle progression. Normal control of pRb activity is frequently lost in human tumor cells, either through mutation in pRb or altered levels of its upstream regulators, including Cdk complexes.

polymerase II to influence the expression of a diverse set of genes.

Compounds that act on multiple Cdk enzymes, together with those that are more selective, have been taken into clinical development. UCN-01 is an example of a nonspecific kinase inhibitor active against a variety of kinases including Cdks, protein kinase C, and checkpoint 1 kinase. In contrast, flavopiridol and R-roscovitine exhibit greater specificity for Cdk targets. Flavopiridol inhibits Cdk1, 2, 4, and 7 (including Cdk2 at nM concentrations) by competing with the ATP binding site, and has reached Phase II clinical trials as a monotherapy for cancer. Roscovitine possesses moderate specificity for Cdk2, but also inhibits other kinases like Cdk7

and Cdk2 at lower potency. In a similar fashion to flavopiridol, roscovitine acts as a competitive inhibitor and induces apoptosis in tumor cells. Roscovitine (also known as CYC 202) has completed a Phase I clinical trial and appears to be well tolerated.

Advances are continuing to be made in improving the selectivity of Cdk inhibitors. For example, a number of oxindole-substituted Cdk inhibitors have greater than tenfold selectivity for Cdk2 against a panel of other Cdks. In this respect, it is hoped that the clinical development of selectively acting Cdk inhibitors will identify molecules with greater efficacy than some of the broad-spectrum agents currently in clinical development.

7 Targeting Chromatin Control in Cancer

Recent advances have highlighted a new and exciting area for therapeutic intervention, namely, the interplay between the cell cycle and chromatin control. Chromatin is the DNA-proteinaceous material in which chromosomal DNA resides in the nucleus. The majority of chromatin proteins is composed of histones that assemble into nucleosomes, and thereby assist in DNA packaging and transcriptional control. The histone tail is subject to a variety of enzymatic modifications, including phosphorylation, acetylation, and methylation, and many of the critical enzymes responsible for these modifications have recently come to light. Histone deacetylases (HDACs) are responsible for removing acetyl groups from lysine residues in histones and many proteins involved in the cell cycle (Fig. 4).

From the perspective of cancer therapy, HDACs have gained recognition as an important target, which, in part, reflects the identification of proteins other than histones that are subject to acetylation control. The activity of cell cycle regulators including E2F, p53, and pRb is influenced by acetylation, and pRb controls E2F activity through the recruitment of chromatin-modifying enzymes, such as HDACs (Fig. 4). Several oncogenic proteins have altered recruitment of HDACs, which leads to aberrant gene transcription. This is exemplified by the fusion protein PML-RARα, which occurs through a chromosomal translocation in acute promyelocytic leukemia (APL). The PML-RARα fusion protein recruits HDAC and represses transcription, causing a block to differentiation and promoting the oncogenic phenotype in APL. Perhaps, not surprisingly, compounds that inhibit HDAC activity cause potent cell cycle effects and frequently induce apoptosis; encouraging results of HDAC inhibitor clinical trials have begun to validate HDAC enzymes as drug targets.

SAHA (suberoylanilide hydroxamic acid) is a small molecule HDAC inhibitor that has reached Phase II clinical trials for the treatment of solid and hematological malignancy, and a range of other HDAC inhibitors are gaining clinical acceptance, for example, PXD101 is a highly potent HDAC inhibitor that blocks proliferation of tumor cells and has entered clinical trials. In addition, a variety of studies have demonstrated the potential for synergy using combinations of HDAC inhibitors with several mechanistically distinct antitumor agents, such as SAHA, which together with radiotherapy, produces an additive effect in human prostate cancer spheroids. While HDAC inhibitors have yet to be completely validated, nevertheless, they do represent

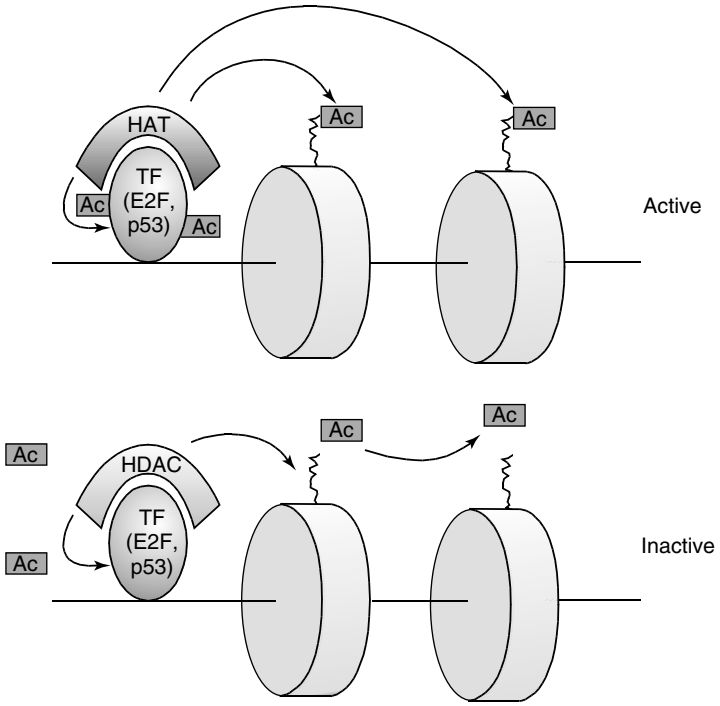

Fig. 4 Acetylation control in the cell cycle. Acetylation (Ac) mediated by acetyltransferases (HATS) can target histone tails in the form of nucleosomes (yellow) or transcription factors (TF) involved in cell cycle control, like E2F and p53. In most cases so far studied, acetylation appears to activate transcription. In contrast, deacetylation mediated by histone deacetylases (HDAC) causes transcriptional inactivity by targeting histones in nucleosomes, leading to a more transcriptionally inert state, together with dampening the activity of transcription factors. (See color plate p. xxv.)

a promising new approach to cancer treatment.

8 Regulating Hsp90

Heat shock protein 90 (Hsp90) is a molecular chaperone that regulates the activity of a variety of cellular proteins, enabling protein folding and preventing denaturation, and perhaps aggregation, of misfolded proteins. Hsp90 is gaining recognition as a cancer target in part because it is overexpressed in a variety of tumor cells and associates with oncoproteins including the tyrosine kinase v-Src, the serine/threonine kinase Raf1, HIF1 (discussed later), and mutated p53. A small molecule inhibitor of Hsp90, geldanamycin, blocks the interaction of Hsp90 with client proteins, including v-Src and Raf1, by interacting with the hydrophobic ATP-binding pocket in the N-terminal region and inhibiting the Hsp90 ATPase activity.

Geldanamycin has been used as a molecular probe to explore the regulation

and composition of Hsp90. Two distinct sets of Hsp90 chaperone are endowed with opposing functions, reflecting the nucleotide occupying the binding pocket. When ATP is present, Hsp90 assembles with the cochaperone proteins p23 and $p50^{Cdc37}$, resulting in the stabilization of client proteins. In contrast, in the presence of ADP, Hsp90 assembles with a different set of proteins, including Hsp70 and $p60^{Hop}$, to promote client protein ubiquitination and degradation via the proteasome (Fig. 5). Binding of geldanamycin to the nucleotide pocket of Hsp90 locks Hsp90 in the form that favors client protein degradation. The mechanism through which Hsp90 causes the degradation of client proteins remains unclear, although E3 ligases that associate with Hsp90 and ubiquitinate some client proteins have been identified. Thus, Hsp90 complexes have opposing functions, and geldanamycin promotes formation of the degrading Hsp90 chaperone complex.

An interesting property of Hsp90 inhibitors observed in preclinical studies is the induction of cytostasis or apoptosis, depending on the cell-type. This may reflect the nature of the Hsp90 chaperone complex and the variation in target client proteins present in cells. Some evidence suggests that the integrity of pRb may dictate sensitivity to Hsp90 inhibition, as cells lacking pRb appear to be quite sensitive to inhibitor-induced apoptosis.

In preclinical studies, Hsp90 inhibitors have shown promising activity. While geldanamycin exhibits levels of hepato-toxicity

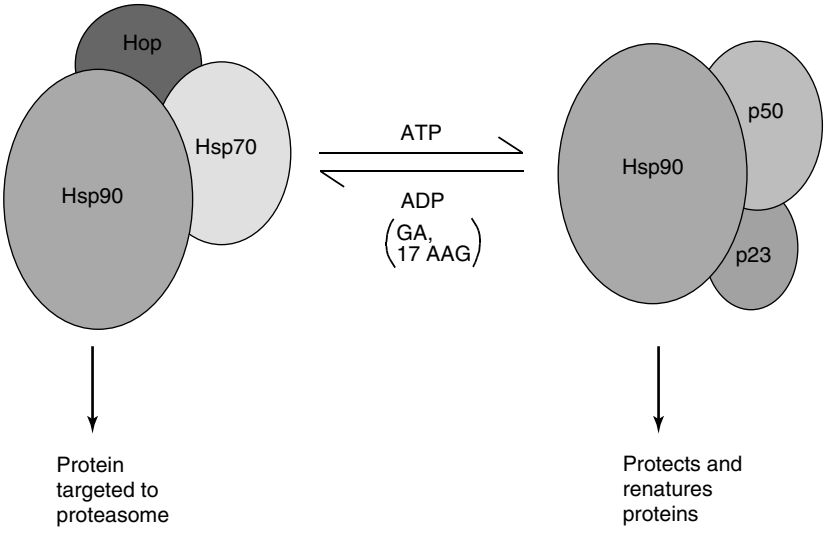

Fig. 5 Regulation of Hsp90 activity. Hsp90 can form different protein chaperone complexes with opposing activities. When ATP is bound to the nucleotide-binding pocket, assembly with p23 and $p50^{Cdc37}$ occurs resulting in a chaperone complex that stabilizes and protects client proteins, whereas ADP in the pocket causes Hsp90 to assemble with Hsp70 and $p60^{Hop}$, resulting in client protein degradation via the proteasome. With geldanamycin (GA) or its derivative 17-allylaminogeldanamycin (17AAG), the chaperone assembles with Hsp70 and $p60^{Hop}$ to favor client protein degradation.

that are too high for clinical application, the derivative 17-allylaminogeldanamycin (17AAG) exhibits improved efficacy, and has now reached phase I clinical trials.

In the clinical setting, if cytostasis were to be the primary outcome of treating a patient with an Hsp90 inhibitor, then sustained chronic administration of the drug may not be possible because of the associated toxicity profile. Conversely, if Hsp90 inhibition causes apoptosis upon short administration, then efficacy with limited toxicity may be achievable. As suggested by Neckers, this situation may be solved eventually by profiling the patient's tumor for the nature and expression level of Hsp90 client proteins. Combined with further information on the appropriate clinical schedule for Hsp90 inhibitors, it may be possible to identify and treat those tumors that will preferentially enter apoptosis upon inhibition of Hsp90 activity. This general principle could be important for other new agents, such as HDAC inhibitors.

9
Blocking Angiogenesis Through Inhibiting HIF1 Activity

Hypoxia-inducible factor 1 (HIF1) plays an important role in regulating angiogenesis by controlling the expression of genes linking vascular oxygen supply to metabolic demand. Tumor progression is associated with higher levels of vascularization that results from the increased synthesis of proangiogenesis factors and decreased synthesis of antiangiogenic factors, and angiogenesis progresses hand-in-hand with the adaptation of tumor cells to growth in low oxygen levels, by increasing glucose transport and glycolysis. HIF1 controls the activity of a variety of genes involved in these processes; for example, the gene for vascular endothelial growth factor (VEGF), which is required for tumor angiogenesis, is regulated by HIF1. Similarly, target genes include glucose transporters GLUT1 and 3, together with enzymes involved in glycolysis like aldolase A and C, enolase 1, and hexokinase 1 and 3.

In cells, HIF1 exists as a heterodimer composed of HIF1α and HIF1β; HIF1β is constitutively expressed, whereas HIF1α is maintained at low levels in most cells under normoxic conditions. While HIF1α is regulated through a multistep process, a key event involves the hydroxylation of specific residues in an oxygen-dependent manner (Fig. 6). The modification of two prolyl residues (P402 and P564) mediates the binding of the von Hippel-Lindau (VHL) protein, which is the targeting component of an E3 ubiquitin ligase that confers degradation on HIF1 through the proteasomal pathway. In hypoxic conditions, prolyl hydroxylation becomes rate limiting, allowing HIF1α to escape degradation to favor increased levels of HIF1α. Further, Lando et al. identified a second hydroxylation-dependent control process occurring in the C-terminal transcriptional activation domain, where an asparagine residue (N803) is hydroxylated by an asparaginyl hydroxylase, which blocks the interaction with the p300 co-activator, again downregulating HIF activity (Fig. 6). Collectively, HIF1α activity is regulated by a series of oxygen-dependent posttranslational modifications mediated by three prolyl hydroxylases and one or more asparaginyl hydroxylases.

Increased activity of the HIF pathway is seen in many tumor types, resulting from the intratumoral hypoxia together with genetic alterations that affect HIF1 control. The impact of genetic alterations on the

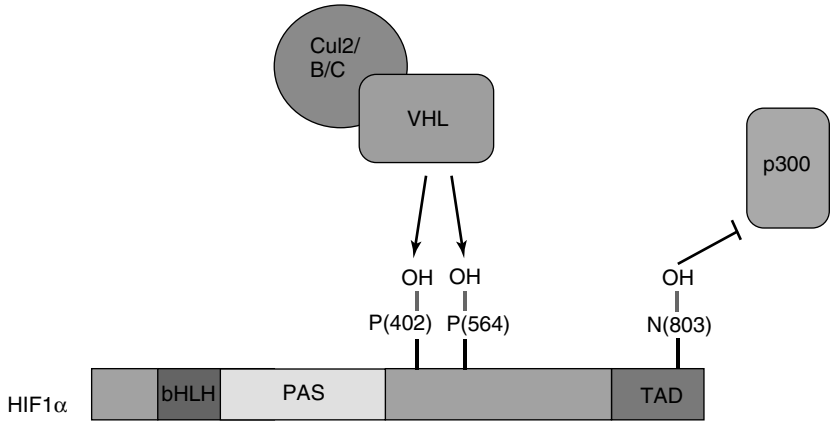

Fig. 6 Regulation of the HIFIα protein. The domains in HIFIα including the basic helix–loop–helix (bHLH) and PAS domains, required for dimerization and DNA binding and the C-terminal trans-activation domain are indicated. Hydroxylation of proline (P) residues at 402 and 564 is required for binding of the von Hippel-Lindau (VHL) tumor suppressor protein, which recruits an E3 ligase (Cul2/B/C complex) that degrades HIFIα. Hydroxylation of the asparagines (N) residue at 803 in the TAD prevents the interaction with p300 and downregulates HIF activity.

activity of HIF1 is influenced by the signal transduction pathway active in the tumor, and may involve pathways regulated by insulin, epidermal growth factor, Ras, or Src. In this respect, VHL is an important component of HIF1 regulation, and inactivation of VHL tumor suppressor activity in VHL hereditary cancer syndrome is characterized by a highly restricted cancer predisposition involving renal cell carcinoma, hemanglioblastoma, and pheochromocytoma. In many other tumors, HIF1α is commonly overexpressed, where its levels sometimes correlate with increased vascular density such as in brain tumors. In other cases, HIF1α overexpression is a marker for aggressive disease, such as cervical cancer. However, it should be borne in mind that HIF1α is not a universal marker for clinical outcome. In ovarian cancer, the overexpression of HIF1α with p53 is correlated with apoptosis, contrasting with the coexpression of HIF1α with mutant p53.

HIF1α is gaining increased acceptance as a potential therapeutic target. The antitumor effect of some chemotherapeutic agents may be derived from effects on the HIF1 pathway. For example, rapamycin inhibits hypoxia-induced HIF1 expression, most likely by blocking the serine/threonine FRAP kinase required for translation of HIF1 mRNA. Agents that target other signaling molecules in the PI3K-AKT-FRAP pathway would similarly be expected to alter HIF1 activity together with many other effects independent of HIF1.

To date, mechanism-based therapeutics that directly target HIF1 are not available. However, a recent Phase III trial supports the therapeutic value of agents that modulate angiogenesis in cancer therapy. The therapeutic antibody, Avastin^{TM}, designed to inhibit VEGF activity, which plays a critical role in tumor angiogenesis, provided a 50% increase in patient survival chance compared to patients

receiving chemotherapy alone. While cancer therapies that inhibit angiogenesis remain in their infancy, clinical studies like the Avastin trial emphasize future potential.

10 Regulating Protein Turnover

Increasing evidence suggests that drugs that influence protein degradation may prove to be beneficial in cancer treatment. As we have discussed, protein degradation plays a crucial role in regulating cell viability, not only in the control of damaged proteins but also in controlling key regulatory processes. The turnover of many cell cycle regulatory proteins is required for normal cell cycle control, for example, the Cdk inhibitor p27 whose degradation is enhanced in certain tumor cells. Similarly, signaling to the NFκB transcription factor is dependent upon protein turnover of its specific inhibitor IκB, allowing NF-κB to activate a variety of genes including cytokines (like tumor necrosis factor) and antiapoptotic proteins.

The proteasome plays a central role in regulating protein turnover. The 26S proteasome is a large multiprotein complex composed of a 20S catalytic complex together with two 19S regulatory subunits that degrade proteins targeted by ubiquitination through the addition of ubiquitin to lysine residues. Ubiquitinated proteins are broken down to short peptides by the central subunit rings of the proteasome, which contain multiple active sites recognizing threonine as the catalytic residue (Fig. 7).

It has become increasingly clear that compounds that block proteasome function possess potential as anticancer agents. The first compounds identified exhibited inappropriate pharmacokinetic properties but ultimately led to the generation of compounds with improved properties, including PS-341 (known as Velcade and developed by Millenium). Velcade has activity across a wide range of tumor cells but appears to act preferentially on tumor cells compared to normal cells. Myeloma cells undergo apoptosis when treated with Velcade, in contrast, for example, to normal bone marrow stromal cells, which exhibit a much reduced sensitivity profile.

Other promising properties of proteasome inhibitors relate to the potential utility in resistant disease. Velcade will arrest the growth of myeloma cells that are resistant to conventional chemotherapies, and overexpression of Bcl2 does not affect the sensitivity of myeloma to Velcade. Velcade was the first proteasome inhibitor to enter clinical trials in hematological malignancy and solid tumors. While the drug is rapidly cleared from plasma (over 90% clearance within 15 min of administration), early indications of efficacy were observed in Phase I trials. Efficacy was subsequently confirmed in a Phase II trial on patients with refractory multiple myeloma. Velcade has successfully completed Phase III clinical trials in multiple myeloma, and is the first proteasome inhibitor to be approved (by the US FDA), for multiple myeloma.

11 Conclusions and Perspectives

We are beginning to see subtle hints that exploiting mechanism-based approaches will deliver improved cancer medicines over many existing chemotherapeutics.

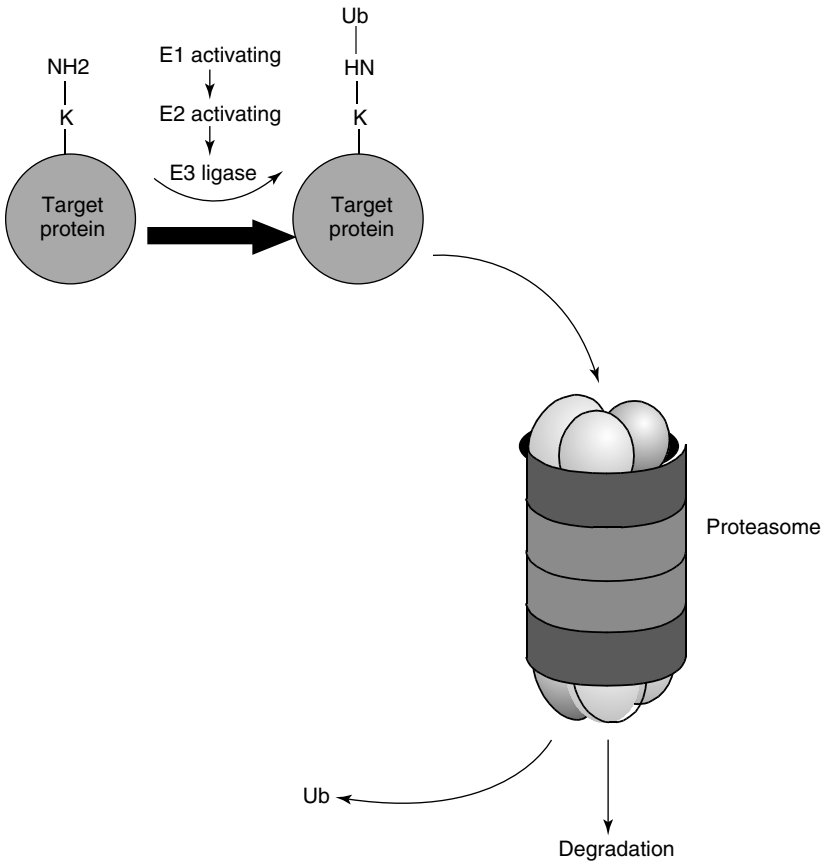

Fig. 7 The proteasome in protein degradation. Target proteins for degradation are ubiquitinated (Ub) at lysine (K) residues through a process involving a ubiquitin-activating enzyme (E1), the transfer of ubiquitin to a conjugating enzyme (E2), which is then transferred to a target protein by an E3 protein ligase. Polyubiquitinated proteins are then recognized and degraded by the 26S proteasome.

Both Gleevec and Valcade directed against the bcr-*abl* tyrosine kinase and the proteasome respectively have shown clinical efficacy. While we await further clinical results with Iressa, HDAC, Cdk, and Hsp90 inhibitor programs, we are left with the compelling view that improved therapies will also arise from these routes of enquiry.

Perhaps, it will be of greater significance to understand the clinical practice with these new cancer agents. Should these compounds be progressed as single agents or, which seems more likely, be applied as combination therapies perhaps with existing cytotoxic agents? It remains a significant hurdle to address this question, and to further provide scientific rationale in considering the array of possible combination options that could be studied. An interrelated question concerns the scheduling regime for administering the drug, particularly in combination therapies, which will reflect knowledge of the critical targets

through which the inhibitor regulates cancer cell growth and the expression of these targets in the particular cancer type. In this respect, we have already discussed the different properties of Hsp90 inhibitors in apoptosis and cell cycle arrest, and how these properties could impact on the clinical regimen and perhaps require patient stratification for maximum clinical benefit.

The possibility of resistance to mechanism-based agents remains to be determined. Tumor cells are adept at acquiring drug resistance phenotypes through diverse mechanisms, and we have already seen clinical resistance to Gleevec, but we await further information before this becomes clinically exemplified for other new agents. Of course, if drug resistance does appear as a clinical hurdle, then it may be possible to modulate its progression by altering drug concentration and exposure through a combination therapy approach.

It is clear that many questions remain to be answered. Nevertheless, we are witnessing an exciting era in cancer drug discovery in which newer drugs are beginning to replace conventional cytotoxic approaches. Our views and anticipations, which are shared by many others, reflect the gathering momentum that translating research knowledge about the cancer cell will yield improved and more efficacious drugs for treating the cancer patient.

Adenocarcinoma of the prostate is one of the most common cancers in men worldwide and is the second leading cause of cancer-specific death in the United States. Over the past 15 years, significant advances have been made in the treatment of prostate cancer, largely owing to earlier diagnosis and the evolution of surgical techniques and improvements in radiation therapy. Nevertheless, tremendous uncertainty and controversy exist regarding the appropriate clinical management of prostate cancer in many cases. Similarly, despite the magnitude of the problem, understanding of the pathogenesis, biology, and natural history of human prostate cancer remains incomplete and unclear. Progress has been made in the past decade in elucidating the molecular and genetic changes involved in prostate cancer development and progression. A better understanding of the underlying disease mechanisms will allow rational treatment strategies and improved outcomes. The classic model of tumor development describes a multistep process in which a series of genetic alterations leads to aberrant, uncontrolled cell growth. This is best characterized in the case of colon cancer, for which specific genetic changes have been correlated with clinical and pathologic disease progression. These genetic alterations can be both hereditary (germ-line mutation) and acquired (somatic mutation). The paradigm is less established in prostate cancer (Fig. 1). We discuss the current understanding of the molecular genetics and biology of prostate cancer development, including genetic predispositions, early changes associated with prostatic intraepithelial neoplasia (PIN), and the traditional classes of genes involved in promoting and repressing cancer development (protooncogenes/oncogenes and tumor suppressor genes, respectively). In addition, we describe recent studies on the role of genetic instability, telomerases, growth factors, cell-adhesion molecules, DNA ethylation, and the androgen receptor (AR) in prostate cancer.

1 Hereditary Factors

Multiple etiologies have been proposed to contribute to the development of prostate cancer. Environmental factors are likely play a major role in most cases; however, inherited genetic factors are clearly important in some men. Epidemiologic analysis of almost 3000 men in the Utah Cancer Registry demonstrated familial clustering of prostate cancer patients, even greater than that for both breast and colon cancer, for which a hereditary component has already been demonstrated. The risks of developing the disease are dependent on both the number of affected first-degree relatives, and early age of disease onset. Using segregation analysis in 691 families, a model of a rare autosomal dominant susceptibility gene with an allele frequency of 0.006 and penetrance of 89% at 85 years of age was proposed. Overall, this gene may account for approximately 9% of all prostate cancer cases but an increased proportion in those patients diagnosed at earlier ages. The criteria for hereditary prostate cancer include a cluster of at least three first-degree relatives with disease, at least two relatives with

prostate cancer diagnosed under the age of 55 years, or prostate cancer in each of three generations in the paternal or maternal lineage.

Genome-wide analysis in 66 high-risk prostate cancer families suggested evidence of linkage to a locus on the long arm of chromosome 1 (1q24-25). This hereditary prostate cancer locus (HPC1) demonstrated linkage in an additional 25 North American and Swedish families studied. The gene has not yet been cloned, but candidate genes in the region include *SKI, ABL2, TRK,* and *LAMC2.* Other reports, however, have shown no evidence of linkage and no significant loss of heterozygosity (LOH) at the *HPC1* locus. Narod and colleagues suggested a recessive or X-linked gene in hereditary prostate cancer. A second prostate cancer susceptibility gene (*HPCX*) has recently been identified, accounting for approximately 16% of hereditary prostate cancer cases. A total of 360 prostate cancer families in North America, Finland, and Sweden were analyzed, and linkage to chromosome Xq27-28 was observed. This finding was confirmed in a study of another 153 families as well as in a study of 104 German prostate cancer families.

RNASEL gene (2′,5′-oligoisoadenylate-synthetase dependent), identified by a positional cloning/candidate gene method, maps to the HPC-predisposition locus at 1q24-q25 (HPC1) and was recently shown to harbor truncating mutations in two families with linkage to HPC1. A nonsense mutation and a mutation in an initiation codon of RNASEL segregate independently in two HPC1-linked families. Microdissected tumors with a germ-line mutation showed loss of heterozygosity and loss of RNase L protein, and that RNASEL activity was reduced in lymphoblasts from heterozyogous individuals compared with family members who were homozygous with respect to the wild-type allele. Thus, germ-line mutations in RNASEL may be of diagnostic value, and the 2-5A pathway might provide opportunities for developing therapies for those with prostate cancer. Thus, there is strong evidence of genetic factors in the potential for development of prostate cancer. The *HPC1* gene may play a role in up to a third of hereditary prostate cancer cases. Further work should identify the *HPC1* and *HPCX* gene products and their functions, as well as other potential prostate cancer susceptibility genes.

2 Genetic Alterations in Precursor Lesions

Histopathologic features of PIN have provided evidence that it represents a precursor lesion of prostate cancer. Changes noted in both high-grade PIN and early invasive prostate cancer include disruption of the basal cell layer, alterations in markers of secretory differentiation, nuclear and nucleolar enlargement, and increased cell proliferation. Identification of similar molecular changes in PIN and prostate cancer further strengthens this hypothesis. Sequential magnification of the abnormalities in PIN is seen in the progression to localized cancer, metastatic cancer, and hormone-refractory cancer. Allelic loss is common in both PIN and prostate cancer (Table 1). Qian and colleagues used centromere-specific fluorescence *in situ* hybridization (FISH) probes against chromosomes 7, 8, 10, and Y, to demonstrate chromosomal anomalies in 50% of PIN and carcinoma foci. Foci of metastatic cancer demonstrated increased chromosomal anomalies. Other alterations of chromosome 8 are common in both PIN and prostate cancer, with gain of chromosome 8q being the most frequent. Using polymerase chain reaction (PCR) and a novel microdissection technique, allelic imbalance of chromosome 8p12-21 in 64% of PIN foci and 91% of cancer foci has been described; no LOH at chromosome 8p12-21 was found in benign tissue. Additional LOH at chromosomes 8p, 10q, and 16q has been identified in 29% of PIN and 42% of primary tumors. Taken together, PIN is a precursor of prostate cancer and exhibits abnormalities in biomarkers,

Prostate adenocarcinoma	7, 8q, 10, X	2q, 5q, 6q, 7q, 8p, 9p, 10q, 13q, 15q, 16q, 16p, 17p, 17q, 18q, 20q, 22q, Y

which likely represent the early genetic changes in prostate cancer progression.

3 Genetic Alterations in Prostate Cancer

Evolution in techniques has allowed more refined analysis of somatic genetic changes in prostate cancer cells. Methods that have been used include cytogenetic analysis, FISH, and comparative genomic hybridization (CGH). More recently, molecular analysis has focused on specific oncogenes and tumor suppressor genes (Table 2), growth factors and their receptors, and the AR. Whereas cytogenetic analysis has yielded important information regarding hematologic malignancies, interpretation of solid tumor karyotypes is more difficult. In addition, prostate cancer is characterized by low mitotic rates, tumor heterogeneity, significant stromal elements, and poor morphology of metaphase spreads. Nevertheless, the most common changes observed are nonrandom loss of the Y chromosome and gain of chromosome 7. Others have observed deletions of chromosomes 7q, 8p, and 10q, as well as structural aberrations of chromosomes 8p22, 10q24, and 1. These chromosomal abnormalities were observed more frequently in poorly differentiated, locally extensive tumors with poor clinical outcomes. Identification of double minutes and homogeneously staining regions, features associated with oncogene amplification, has been rare in prostate cancer specimens. FISH and CGH data have confirmed cytogenetic findings and enabled detection of additional areas of change in prostate cancer cells. Aneuploidy occurs in 66 to 100% of prostate cancers. The most common alterations include chromosome 8 (23%) and chromosome 7 (20%), with involvement of chromosomes 10, 12, X, and Y occurring less frequently. Aneuploid tumors demonstrated more frequent disease progression, most notably with chromosomes 8 and Y, and may have use as prognostic markers for locally advanced prostate cancer. Chromosome 7 trisomy was noted more often in tumors of higher stage and Gleason grade. Others have postulated that S-phase fraction, like DNA ploidy, correlates with both pathologic features and clinical outcomes. However, the importance of both DNA ploidy and S-phase fraction over standard clinical and pathologic information remains unclear. Comparative genomic hybridization allows genome-wide survey for regions of amplification or loss by hybridizing DNA from normal and tumor tissues with normal metaphase

chromosomes. Alterations as detected by CGH are present in up to 70% of prostate cancer cases, with losses five times more common than gains. Areas of losses involve chromosomes 2q, 5q, 10q, 13q, 15q, 16q, 16p, 17p, 17q, 18q, 9p, 20q, and Y, whereas gains involve chromosomes 11p, 1q, 3q, 9q, 20, 23, and 2p. New alterations revealed by CGH include loss at chromosomes 6q, 9p, and 22q and amplifications at chromosome 8q24. FISH and molecular methods of restriction fragment length polymorphism and PCR have generally confirmed these regions of change detected by CGH. The more frequent finding of DNA loss suggests that inactivation of tumor suppressor genes in these areas may play an important role in prostate cancer development. More recent studies have specifically examined alterations in Y chromosome number. It was found that prostate cancer cell lines were able to consistently induce an increase in the number of copies of the Y chromosome in three murine tumor cell lines *in vivo*. FISH demonstrated that the majority of cells had two to three copies of the Y chromosome and that the amplification was specific, without other chromosomes being involved. However, significant changes were not found in Y chromosome number. Using touch preparations from prostate tumors, 42 specimens were analyzed by whole Y chromosome paint FISH. Only a single case of Y chromosome gain, and no evidence of loss of the entire Y chromosome, was found.

4 Tumor Suppressor Genes

Cancer development relies on alterations in normal homeostatic mechanisms exhibiting precise control on cellular proliferation. The genes involved in negative regulation of cell growth can be disrupted, thus allowing tumorigenesis. These tumor suppressor genes are recessive and typically require inactivation of both alleles. As mentioned, sites of chromosomal deletion from LOH studies may suggest the presence and location of tumor suppressor genes. Loss of part, or all, of the short arm of chromosome 8 (8p) is the most common genetic defect in prostate cancer and has been confirmed by several studies. Loss of heterozygosity studies in other cancers such as lung, colon, and breast also demonstrate frequent chromosome 8p loss, further suggesting the presence of a potential tumor suppressor gene that may be fundamental in tumor development. Smaller regions of deletion, chromosomes 8p11-12 and 8p22, have been reported. Only recently has a candidate tumor suppressor gene been identified from the chromosome 8p22 region. This *N*33 gene, expressed in most tissues, is downregulated in colon cancer cell lines; however, studies in prostate cancer cell lines have not revealed mutations in *N*33 or evidence of downregulation. No other candidate tumor suppressor gene has been reported in these regions. Another frequent site of loss, initially described by classic cytogenetic analysis, is the terminal region of chromosome 10q (10q24-25). A potential tumor suppressor gene, *MXI1*, has been mapped to this chromosomal region. The protein acts as a negative regulator of the *MYC* oncogene, and its inactivation may potentially result in increased activity of the MYC protein. Mutations of the *MXI1* gene have been found to be rare, and it has been demonstrated that the allelic losses of chromosomes 10q24-25 occur near the chromosome 10q23-24 boundary and not at the *MXI1* locus. 44, 45 P53 is one of the

most widely studied tumor proteins, and abnormalities of the *P53* tumor suppressor gene are the most common genetic alterations associated with human malignancy. P53 plays a key role in the regulation of the cell cycle, ensuring DNA integrity by negatively affecting cell growth after DNA damage (Fig. 2). Overall, the incidence of LOH and mutations at the *P53* locus (chromosome 17p13.1) in prostate cancer is less than in other malignancies, ranging between 10 and 30%. Evidence suggests that changes in P53 are important in the subset of patients with advanced disease and thus may be a late event. Studies of cell lines derived from metastatic deposits demonstrated frequent *P53* mutations, and transfection of wild-type P53 resulted in suppression of growth. Ability to detect P53 by immunohistochemistry often accompanies mutations in the gene caused by increases in the protein half-life, thus allowing study of paraffin-embedded specimens. Nuclear accumulation of P53 correlated with metastatic disease or androgen independence. In addition, P53-positive tumors were found to have a greater frequency of *P53* mutations. These mutations are primarily localized to exon 7. An association between P53 expression and poor clinical outcome has been reported. Moreover, alterations in P53 may affect and therefore predict response to radiation therapy. Several regulatory genes, including *P53*, *BCL2*, *CMYC*, and *RAS*, have been implicated in the apoptotic process. It is postulated that defects in these genes may limit the ability of cells to induce apoptosis; thus, partial resistance to agents that act through programmed cell death may be imparted with P53 alterations. Several studies demonstrate an attenuated response to ionizing radiation in cells harboring *P53* mutations. Similarly, *P53* mutations adversely predict overall survival in patients with locally advanced disease treated with androgen deprivation after radiotherapy. Impaired apoptosis, after either radiotherapy or androgen ablation, may be important in tumors with *P53* mutations. Variations in studies of P53 may result from many factors. First, commercially available antibodies recognizing P53 differ in sensitivity and specificity. Second, quantification of P53 staining is subject to interobserver variability. Third,

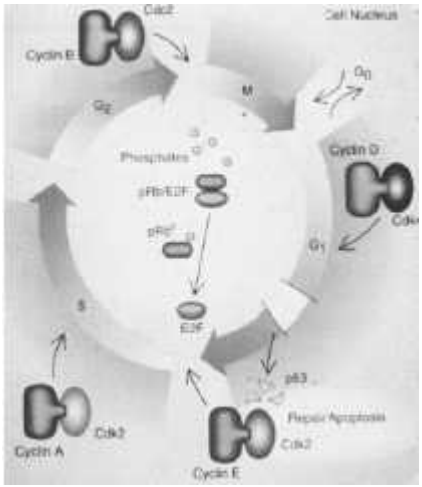

Fig. 2 Overview of the role of P53, RB, and related proteins in the cell cycle and regulation of apoptosis.

ability to detect *P53* mutations is dependent on the technique used, such as temperature or denaturing gradient gel electrophoresis or single-stranded conformation polymorphisms. In addition, heterogeneity in the distribution of *P53* alterations can result in variations, depending on which regions of the tumors are examined. The retinoblastoma tumor suppressor gene (*RB1*) is associated with the development of retinoblastoma in the immature retina as well as tumors of the breast and lung. Because of the frequent LOH of chromosome 13q (30 to 35%) and the location of *RB1* at chromosome 13q14, *RB1* has been postulated to be a tumor suppressor gene involved in prostate tumorigenesis. The phosphoprotein likely interacts with transcription factors, such as the E2F family, and negatively regulates cell growth. Although decreased or absent RB protein expression was found in a third of tumors with LOH, few mutations of the *RB1* gene have been identified. The DU145 cell line possesses a mutated *RB1* gene, and reintroduction of wild-type *RB1* is able to reduce tumorigenicity. Using single-stranded conformation polymorphism analysis of ribonucleic acid (RNA), Kubota and colleagues revealed that 4 of 25 primary cancers (16%) had *RB* alterations. Interestingly, LOH at *RB* has been found not only in cancer specimens but also in benign prostatic hyperplasia (BPH) samples. More recent data do not demonstrate prognostic significance of altered RB protein expression. The true importance of *RB1* and exact nature of LOH at 13q remain to be determined. Another region at chromosome 13, 13q21, has also been found frequently deleted in various human cancers including prostate cancer. Frequent genomic deletion and loss of expression as well as cell growth suppression indicate that KLF5 is a reasonable candidate for the tumor suppressor gene at 13q21 in prostate cancer.

In prostate cancer, chromosome 18q locus LOH has been reported in up to 45% of primary tumors. The deleted locus in colorectal carcinoma (*DCC*) gene is a candidate tumor suppressor gene located in this region and possesses homology with neural cell-adhesion molecules. Although mutations of the gene have not been reported, decreased expression of the *DCC* gene, as well as allelic loss, suggest a role in prostate cancers. It has been suggested that alternative tumor suppressor genes may be located at chromosome 18q21.

Pentaerythritol tetranitrate (PTEN) (the phosphatase and tensin homolog deleted on chromosome-10), a dual specifity phosphatase, is a tumor suppressor gene whose inactivation has been associated with many different types of cancer including prostate cancer. Combined loss of PTEN and p27 expression is associated with tumor cell proliferation by Ki-67 and increased risk of recurrent disease in localized prostate cancer.

5 Oncogenes

The second major class of genes implicated in tumor development is the so-called oncogenes. Initially recognized in cells transformed by retroviruses, oncogenes are derived from normal cellular genes, or proto-oncogenes, that contribute to tumorigenesis once activated by mutation or increased expression. The typical functions of these proto-oncogenes in normal cells include control of differentiation and proliferation. The critical role of oncogenes has been well documented

in many malignancies. Unlike other cancers, though, prostate cancer initiation and progression do not predominantly rely on oncogenes. As discussed above, genetic losses are much more common than DNA amplification. Nevertheless, region 8q, specifically 8q24, is the only region to demonstrate significant gain or amplification (5 to 16%). *MYC*, located at chromosome 8q24, is a member of the *MYC* proto-oncogene family. *MYC* encodes a nuclear DNA-binding phosphoprotein involved in transcriptional regulation and is frequently amplified in breast, lung, and cervical cancers. Amplification, rearrangement, and overexpression of *MYC* has been documented in the LNCaP cell line but not in primary tumor specimens. Elevated *MYC* expression has been shown in prostate cancer, compared to BPH, by Northern blot analysis. Others have suggested that higher *MYC* levels, seen with higher grades and lymph node metastases, correlate with biologic aggressiveness. Reporter gene and mobility shift assays demonstrated that c-Myc could repress *TMEFF2* gene (a transmembrane protein that can inhibit prostate cancer cell growth) expression through its cognate site. In light of the role of *TMEFF2* in inhibiting cell growth, its suppression may contribute to the oncogenic properties of c-Myc. Conflicting data from *in situ* hybridization do not confirm any role of *MYC* in prostate cancer, and additional studies are required. Another oncogene, *ERBB2* or *HER2/NEU* located at chromosome 17p21, has been studied in prostate cancer. The proteins in the *ERBB* family are transmembrane receptors with tyrosine kinase activity, including the *ERBB1* gene encoding the epidermal growth factor (EGF) receptor. *ERBB2* is implicated in cancers of the breast and ovaries and is typically overexpressed as a result of gene amplification or transcriptional and posttranscriptional processing. The results do not clearly show increased ERBB2 expression in prostate cancer; some have found higher protein expression in prostate cancer, whereas others demonstrate overexpression in BPH. Similarly, the prognostic value of *ERBB2* amplification and P185*NEU* protein expression is controversial. The finding of P185*NEU* in PIN and carcinoma by immunohistochemistry suggests that *ERB* oncogenes may be an early event in prostate transformation and provide further evidence for PIN as a pre-neoplastic state. Fourteen molecular studies do agree that *ERBB2* amplification is not the mechanism of activation in prostate cancer. As with P53 studies, technical factors, such as method of antigen retrieval and type of antibody used, may significantly influence the results of immunohistochemical staining. It has recently been demonstrated that FISH is more sensitive in the detection of *HER2/NEU* abnormalities, and further studies should investigate the use of this method. Recent studies suggest that ErbB1/ErbB2 RTKs play an important role in the biology of androgen-independent prostate cancer and provide a rationale for clinical evaluation of inhibitors targeted to this pathway. Analysis for Her-2 may improve prognostic algorithms for clinically relevant endpoints other than biochemical relapse.

The *RAS* oncogene family is involved in a wide variety of human cancers. The three proteins (H-RAS, K-RAS, and N-RAS) are guanosine triphosphate binding proteins essential for signal transduction. Point mutations within codons 12, 13, and 61 are the most common activating changes found that lead to uncontrolled cell growth. Immunohistochemistry has suggested high levels of RAS expression in prostate cancer; overexpression correlates

with progression and metastatic disease rather than with tumor initiation and has limited value in diagnosis and staging. *RAS* mutations, detected by molecular techniques, are rare in Western populations (<5%) and almost absent in localized prostate cancer. In Japan, however, mutations in the *RAS* gene have been found in up to 25% of cases. These data suggest that different mechanisms of prostate cancer initiation and progression may exist within different ethnic or geographic groups. Recent studies showed that stable expression of Ras effector-loop mutants that activate the Ras/MAP kinase pathway is sufficient to reduce the androgen requirement of LNCaP prostate cancer cells for growth, prostate-specific antigen (PSA) expression, and tumorigenicity; and attenuation of Ras signaling restores androgen sensitivity to hormone-refractory C4-2 prostate cancer cells.

6 DNA Repair Genes

The classic paradigm of tumor development involves oncogenes and tumor suppressor genes. More recent research describes a third class of genes that lead to tumorigenesis, those involved in DNA repair. Maintenance of genomic integrity is essential to prevent the acquisition of mutations; thus, genetic instability allows accumulation of changes, which may lead to tumor formation. It has been estimated that mutation in up to 100 genes can result in genomic instability. Efforts have focused primarily on microsatellite instability, originally described in hereditary nonpolyposis colorectal cancer (HNPCC). Mutations, either inherited or acquired, in DNA mismatch repair genes lead to the replication error phenotype (RER). Several of these genes have been identified in humans (*MSH2, MLH1, PMS1, PMS2*) and are homologous to the same genes in yeast. Defects are manifested by variations in the lengths of noncoding mono-, di-, tri-, and tetranucleotide repeats, the so-called microsatellites. Whereas microsatellite instability is found in HNPCC as well as sporadic colorectal, endometrial, stomach, and pancreatic cancers, the frequency in prostate cancer ranges from 5 to 70%. Two studies reported high frequency of alterations at specific microsatellite loci, although microsatellite instability at multiple loci is rare in prostate cancer. We found frequent microsatellite instability (45%) in prostate cancer using normal and tumor cells of 40 microdissected prostate cancer specimens. It is essential to use pure epithelial cells isolated by microdissection from 5-μ sections of prostate tissue. Variations in results may be the product of differences in PCR primer and tissue selection as well as definitions of RER. Recent reports have not found the RER phenotype in prostate cancer, with the more common finding being focal instability and the lack of widespread microsatellite instability. Evidence of microsatellite instability in 19% of cancers has been found, with no difference between clinically apparent tumors and incidentally discovered cancers at transurethral prostatectomy. In an analysis of 10 loci in 60 prostate cancers, 113 RER was found in both areas of cancer and PIN but rarely in areas of glandular hyperplasia. Racial differences have been noted in the frequency of microsatellite instability. Another report suggested that the frequency of RER is much higher in the United States when compared with Japan. The DU145 cell line demonstrates microsatellite instability and mutations in *MLH1* and *PMS2*. Overall, RER is not

predominant in most prostate cancers but may be associated with high-grade and advanced tumors, although this remains controversial.

7 Telomerase

Telomeres are repetitive, noncoding DNA sequences found at the ends of all eukaryotic chromosomes that play a role in protection and replication of the chromosomes, as well as prevent loss of genetic coding regions. In humans, hundreds of TTAGGG tandem repeats compose the telomeres. Normal cells lose between 50 and 200 of these nucleotides at each mitosis and, after 50 to 100 cell doublings, a critical amount of sequence is lost and the cells senesce. Thus, telomeres and their shortening serve as a mitotic clock. Telomerase, a ribonucleoprotein enzyme, is able to add telomeric sequences to the ends of newly replicating DNA and can compensate for telomere shortening. Germ-line cells and fetal cells typically have high telomerase activity, whereas normal somatic cells have undetectable telomerase activity. It is postulated that increased telomerase activity allows unlimited cell division and, therefore, is associated with cellular immortalization, an important phenotypic feature in the progression of normal cells to malignant ones. Normal prostate tissue does not exhibit telomerase activity. In an assay of benign and malignant tissue for telomerase activity using a sensitive PCR technique, a large number (84%) of cancers were strongly positive, as well as all lymph nodes with metastases. All human prostate cancer cell lines tested (DU145, LNCaP, PC3, PPC1, TSU) demonstrated telomerase activity. In contrast, no normal tissue from the cancer specimens or BPH samples from patients without evidence of cancer demonstrated telomerase activity. Benign prostatic hyperplasia tissue adjacent to areas of cancer demonstrated weak telomerase activity in 12% of cases. Paradoxically, telomere length from cancer tissue was significantly and consistently shorter than that detected in either adjacent normal or BPH tissue. Other studies have confirmed the high incidence of telomerase activity in prostate cancer, and some data suggest a correlation with Gleason grade. Interestingly, telomerase activity has been found frequently in adjacent areas of PIN (74%). These findings lead to several conclusions. First, telomerase activity in a majority of PIN and cancer further supports the hypothesis than PIN is a precursor of cancer and harbors early genetic changes. Second, telomerase activity is nearly ubiquitous in prostate cancer, and expression occurs early in prostate carcinogenesis. Third, the finding of telomerase activity in associated areas that appear histologically normal suggests that telomerase activity may be useful as a sensitive diagnostic marker for malignant tissue prior to visible, microscopic changes. The relationships between telomerase activity and expression levels of human telomerase RNA (hTR) and human telomerase reverse transcriptase (hTERT) mRNA in benign and malignant alterations of the human prostate gland has been investigated. Remarkably, one-third of all cancer and BPH tissue samples with hTR and hTERT expression lack telomerase activity. Quantitative analyses contradict the assumption that a certain threshold level of hTR or hTERT mRNA is required for telomerase activation, thus indicating that telomerase regulation in prostate cancer occurs more likely on a posttranscriptional level. Nevertheless, the observation

that hTR and hTERT mRNA levels are significantly ($p < 0.002$) correlated suggests some common mechanisms in the upregulation of hTR and hTERT expression. Because *in situ* hybridization revealed strong hTERT expression not only in all cells of the tumor glands but also in high-grade PIN foci, this upregulation seems to occur early in prostate carcinogenesis.

8 Growth Factors

Growth factors in the prostate have been studied in two settings: the production of factors within the tissue and the effects of exogenous factors on prostate cells in culture. It should be noted that virtually all studies relating to growth factor expression have been performed in normal adult prostates, which are either growth quiescent or only slowly growing. However, one report used prostates from young rats (6 to 8 weeks) to characterize expression of heparin-binding growth factors. Most studies in human tissue have used BPH specimens from older men, in whom growth is exceedingly slow. Thus, the function of growth factors in the adult prostate, as determined by current data, is likely more homeostatic than stimulatory. Further description of growth factor expression in the growing prostate is required to clarify these issues and inconsistencies. Polypeptide growth factors and their receptors play a role in both normal prostate growth and prostate cancer development. These growth factors act in either an autocrine or paracrine fashion and play a role in stimulating or inhibiting proliferation, differentiation, development, chemotaxis, and tissue repair. They are divided into four major families: EGF, fibroblast growth factor (FGF), insulin-like growth factor (IGF), and transforming growth factor-α (TGF-α). The EGF family includes EGF, TGF-α, amphiregulin, heparin-binding EGF, and *cripto*. Both EGF and TGF-α have been implicated in prostate cancer and act on the EGF receptor in a paracine manner. Autocrine stimulation of the EGF receptor may also be important in the regulation of prostate epithelial proliferation and differentiation, although this remains controversial. Prostate cancer cell proliferation is strongly reduced by the EGF receptor tyrosine kinase inhibitor ZD1839 *in vitro* on human cell lines and primary cultures. TGF-α whose overexpression in transgenic mice results in hyperplasia and dysplasia of the anterior prostate, has been found in tumor cells but not in normal prostatic cells.

The FGF family has at least 9 members; only FGF1, 2, 3, 7, and 8 have been found in prostate tissue. Moreover, their role in prostate cancer is currently unclear. Increased expression of both FGF7 and FGF8 has been reported in adenocarcinoma and was associated with hormone-refractory disease and higher grade, respectively. Interestingly, the stroma produces FGF7 exclusively and is the site of most FGF messenger RNA (mRNA) expression. This further confirms the vital role of the prostatic stoma and fibroblasts in affecting epithelial cell behavior and carcinogenesis. In the presence of an active AR, the combined production of FGF2 and FGF-BP may play an important role in the progression of prostate cancer through the selection of AR-clones expressing high levels of Bcl-2. By using the Transgenic adenocarcinoma mouse prostate (TRAMP) model, the expression of FGFR1iiib in intraductal vasculature and the expression of FGF-2 protein were found to be concomitant with the emergence of

PIN. These observations implicate specific changes in the FGF axis with the initiation and progression of prostate cancer, and underscore the utility of animal models to identify specific molecular changes in early disease. Fibroblast growth factor, also known as keratinocyte growth factor, is expressed only by epithelial cells, and studies in the developing mouse seminal vesicle have shown it to be an important paracrine mediator of androgen action. Similar effects may be important in prostate cancer and in epithelial cell proliferation and morphology.

The IGF family, comprised of IGF-I, IGF-II, and relaxin, is involved in cell growth, cell division, and apoptosis. Insulin-like growth factor-II is an autocrine and paracrine regulator of cell proliferation in the adult prostate. In androgen-insensitive prostate cancer, the IGF-I receptor is overexpressed, and IGF-II autocrine stimulation results in uncontrolled proliferation. Typically, the IGF-II gene demonstrates imprinting, in which one allele is inactivated and silent. Bi-allelic expression in cases of cancer has been reported and it has also been suggested that loss of imprinting may be involved in abnormal growth in prostatic tissue. The Physician's Health Study prospectively examined a matched population of 152 men for IGF-I. The study concluded that higher plasma IGF-I levels were associated with higher rates of prostate cancer; men in the highest quartile were 4.3 times more likely to develop prostate cancer. These findings were independent of PSA level, stage, and grade. The TGF-β family has three isoforms in humans and regulates cell cycle kinetics by acting on RB, MYC, and cyclin-dependent kinase inhibitor activity. Transforming growth factor-β, detected in normal and neoplastic prostate tissue, is an inhibitor of normal prostate epithelial cell growth, and its activity is modulated by other growth factors, androgens, and the extracellular matrix. Conversely, TGF-β can also stimulate cell growth and contribute to tumor aggressiveness. Immunohistochemistry revealed increasing levels of TGF-β1 in tumors with metastatic and nodal involvement. Plasma TGF-β1 levels may have use as a tumor marker or predictor of clinical prognosis. The TGF-β effects are mediated through the heteromeric complex of the type I and II receptors. Thus, loss of function of either receptor results in resistance to TGF-β inhibitory signals. Decreased levels of type I and II receptors are correlated with higher grade and advanced disease. Activation of TGF-β signaling in human prostate cancer cells suppresses tumorigenicity via deregulation of cell cycle progression and induction of caspase-1 mediated apoptosis.

Other growth factors implicated include hepatocyte growth factor, platelet-derived growth factor, nerve growth factor, and interleukin-6. Further investigation is required to elucidate their exact roles in prostate carcinogenesis.

9 Metastasis Suppressor Genes

The invasive nature of prostate cancer is dependent on the loss of usual cell–cell and cell–matrix interactions. Several candidate genes involved in this process have been identified in prostate cancer that typically act as tumor suppressor genes. Ultimately, a metastatic phenotype may be acquired after inactivation of one or many of these genes. As discussed above, loss at chromosome 16q, as detected by all methods, is frequent in prostate cancer and led to the search for a tumor suppressor

gene. E-cadherin, located at chromosome 16q22.1, has been studied thoroughly. The protein is a calcium-dependent, epithelial cell–cell adhesion molecule and plays a vital role in the invasive potential of cancer cells (Fig. 3). Decreased E-cadherin expression is found in prostate cancer and is associated with higher grade and worse clinical outcome. In addition, metastases express less E-cadherin than primary tumors. Blocking E-cadherin function using antibodies or antisense transcripts increases invasive behavior. Conversely, reexpression of E-cadherin in epithelial cells can induce a reversion to a noninvasive phenotype (Fig. 4). Newer techniques in immunohistochemistry may reduce the inconsistencies from formalin fixation and autolytic artifacts that characterized prior studies. An alterative approach has been described for fixing prostatectomy specimens that yields samples amenable to E-cadherin immunohistochemistry as well as extraction of longer DNA fragments.

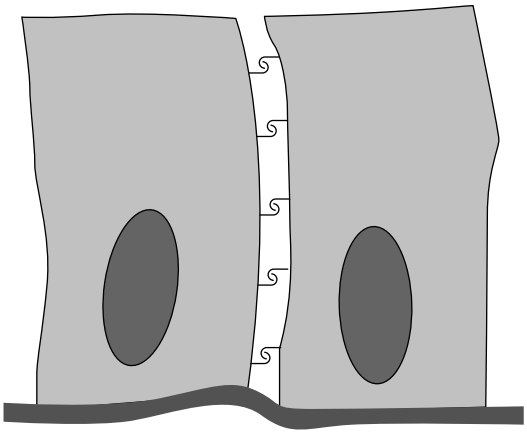

Fig. 3 Illustration depicting the role of E-cadherin. The surface molecule interacts with other E-cadherin molecules, contributing to epithelial cell adhesion. The cytoplasmic domain, not shown, normally interacts with intracellular catenin proteins.

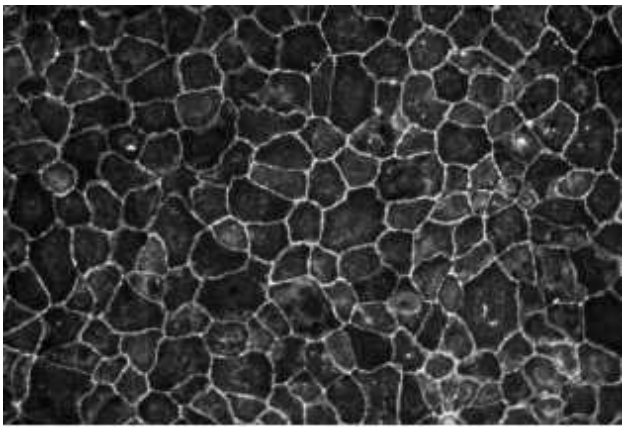

Fig. 4 Immunocytochemistry after staining using an antibody to E-cadherin. The immortalized, but nontumorigenic, prostate epithelial cells demonstrate strong staining for E-cadherin in the areas of cell–cell adhesion.

Mutations in the E-cadherin gene (*CDH1*) are rare, suggesting other mechanisms of regulation and inactivation. Hypermethylation of the 5′-CpG islands of *CDH1* may silence the gene, and this has been found in E-cadherin–negative cell lines. After treatment with demethylating agents, E-cadherin RNA and protein levels were partially restored. E-cadherin function is also dependent on sex steroids, which increase expression, and interaction with cytoskeletal and other adhesion molecules such as the catenins. The catenins are a family of three (α-, β-, γ-) proteins involved in intercellular adhesion and signal transduction. They associate with the cytoplasmic domain of E-cadherin to allow coupling to the microfilament cytoskeleton. Because of frequent chromosome 5q losses and mapping of α-catenin (*CTNNA1)* to chromosome 5q21-q22, they are of particular interest. The PC-3 cell line expresses E-cadherin; however, α-catenin is absent owing to homozygous deletion of the gene. Reexpression of α-catenin by either transfection with α-catenin complementary DNA or transfer of chromosome 5 was associated with a return of cell–cell contact and decreased tumorigenicity in mice. Thus, both E-cadherin and α-catenin function is required in reducing invasive potential. Like E-cadherin, loss of α-catenin expression, as determined by immunohistochemistry, predicts invasiveness and poor prognosis. Further study is needed of β- and γ-catenin. Only 5β-catenin mutations in 104 specimens have been found. In addition, the adenomatous polyposis gene product (APC) interacts with β-catenin. APC is also located at chromosome 5q21, and inactivation may lead to altered cell–cell function. Other epithelial cell-adhesion molecules may act as repressors of growth and invasion. One that has been evaluated is CCAM, a member of the immunoglobulin gene superfamily. CCAM expression in human prostate cancer cells reduces anchorage-independent growth and tumor invasion *in vitro* and *in vivo* respectively. Antisense CCAM expression in less tumorigenic cell lines was able to increase tumorigenicity. Studies in human tissue reveal absence of CCAM in prostate cancer and decreased staining in BPH and high-grade PIN. Members of the integrin family mediate interactions between cells and extracellular matrix proteins, affecting cell migration, proliferation, and invasion. These heterodimeric cell-surface receptors are composed of noncovalently associated α- and β- subunits. Overall, downregulation of the various integrin subunits occurs in prostate cancer development. These include α2, α4, α5, αv, and β4. Conversely, increased expression of integrin α6 is associated with more invasive activity. An increased invasive phenotype in prostate cancer is associated with $\alpha 3\beta 1$, $\alpha 4\beta 1$, and $\alpha 6\beta 1$. More recently, it has been found that $\alpha v\beta 3$ integrin expression in prostate cancer generates a migratory phenotype, which is modulated by a focal adhesion kinase signaling pathway. Other integrins, $\alpha 6\beta 4$ and $\alpha 2\beta 1$, attach the cells to the basement membrane and bone matrix, respectively. The *KAI1* metastasis suppressor gene is found on chromosome 11p11.2. It belongs to a family of membrane glycoproteins and is thought to participate in cell–cell interaction and cell migration. KAI1 is expressed in normal human prostate epithelial cells but is absent in cell lines derived from metastases, such as DU145, PC-3, and LNCaP. Reintroduction of the *KAI1* gene into the Dunning rat AT6.1 cell line suppressed the metastatic potential. Downregulation of KAI1 is found in the progression of prostate cancer, with decreased protein expression in 70% of

primary cancer specimens and in almost all patients with lymph node metastases or hormone-refractory disease. A recent study showed that KAI1 expression could be a predictor of stage A prostate cancer progression. Allelic loss or mutations do not appear to be the mechanism of KAI1 decrease. EWI2/PGRL, a KAI1 associated protein, was recently found to be important for KAI1-mediated suppression of cancer cell migration.

Located near *KAI1*, CD44 is a transmembrane protein associated with cell–cell and cell–extracellular matrix interactions. Conflicting data exist regarding CD44's function in prostate cancer. Loss of expression of CD44 standard isoform (CD44s) correlated with poor prognosis in several studies, whereas others demonstrate increased CD44 expression associated with high-grade and metastatic potential. Neutralizing antibodies to CD44 inhibited cell proliferation and basement membrane invasion. In another report, transfection-enhanced expression suppressed metastatic ability in the AT3.1 cell line without affecting *in vivo* growth or tumorigenicity. Recent study indicates the important role of CD44 methylation in the progression and metastasis of prostate cancer. Pentaerythritol tetranitrate is a tyrosine phosphatase, mapping to chromosome 10q23 that negatively regulates cell migration and cell survival. In addition, its homology to a protein that interacts with actin filaments at focal adhesions suggests that PTEN may regulate cell invasion and metastasis. Loss of *PTEN* may occur in 13 to 37% of primary prostate cancers. Increased frequency of mutations and LOH is found in cases with metastases. Recent immunohistochemistry confirms these observations. Total absence of PTEN expression correlated significantly with Gleason score and advanced pathologic stage. Pentaerythritol tetranitrate, along with CD44 and KAI1, has potential as a marker to evaluate the metastatic ability of prostate cancer, and further studies are warranted.

10 DNA Methylation

Abnormal patterns of DNA methylation often characterize human cancer cells. These include hypermethylation, redistribution of methylation, and demethylation of normally methylated regions. Although hypomethylation has been reported in prostate cancer, its significance is unclear. More recently, hypermethylation of particular areas has been noted and characterized. The most important sites of hypermethylation are the CpG islands, with a high density of C-G dinucleotide sequences, found in the 5′ regions of genes. Methylation of CpG-rich islands may be associated with transcriptional inactivation of the associated gene. This has been demonstrated for the CDKN2 (*P16*) gene at chromosome 9p21. The product, a cyclin-dependent kinase inhibitory protein, controls passage through the G1 phase of the cell cycle. Inactivation by homozygous deletion, found in 20% of prostate specimens studied, may induce progression through the cell cycle in tumors. Analysis of the CpG-rich promoter region in exon 1 of *P16* in the prostate cancer cell lines PC-3, PPC1, and TSU revealed dense methylation in these areas. In addition, this hypermethylation correlated with lack of mRNA expression as determined by reverse transcriptase PCR. *In vitro* treatment with the demethylation agent 5-aza-2′-deoxycytidine induced reexpression of CDKN2 transcripts. Promoter methylation has been found in 13

and 8% of primary and metastatic tumor samples, respectively, whereas no normal prostate tissues were methylated at the CDKN2 gene promoter. Gu and colleagues were unable to demonstrate intragenic alterations in methylation pattern in early-stage cancers, suggesting that *P16* methylation may be involved in disease progression rather than initiation. The π-class glutathione-S-transferase (*GSTP1*) gene at 11q13 is important in the pathway, preventing damage from electrophilic metabolites of carcinogens and reactive oxygen species. Decreased GSTP1 expression was found to accompany human prostate carcinogenesis. Analysis of a CpG island in the promoter region of the *GSTP1* gene revealed hypermethylation in all prostate cancer specimens examined but no aberrant methylation in 12 nonmalignant tissues, including BPH. Further immunohistochemistry in 91 cases of cancer was unable to detect GSTP1 expression in almost all samples (97%). These findings were confirmed *in vitro*, with protein expression limited to prostatic cell lines with *GSTP1* alleles hypomethylated at the promoter sequences. Additional work has substantiated that CpG-island hypermethylation is abnormal in both alleles in most prostate cancers; in normal tissue, the entire CpG island is unmethylated with extensive methylation outside the *GSTP1* gene. *GSTP1* hypermethylation and associated reduction in GSTP1 expression have also been demonstrated in areas of PIN. The high frequency of *GSTP1* CpG hypermethylation may serve as a biomarker in prostate cancer detection and staging. Recent study on quantitation of GSTP1 hypermethylation can accurately detect the presence of cancer even in small, limited tissue samples. It represents a promising diagnostic marker that could be used as an adjunct to tissue biopsy as part of prostate cancer screening.

Another locus of hypermethylation in the prostate has been found to be methylated in cancer (*HIC1*) gene on chromosome 17p13.3. The methylation of NotI restriction sites at D17S5 is a common occurrence in prostate cancer and is thus postulated to be an important step in carcinogenesis. However, nonmalignant prostate, but not seminal vesicle tissues also demonstrated *HIC1* hypermethylation, suggesting that the locus, and its tissue-specific methylation, may be important in the organ's susceptibility to uncontrolled growth. The CpG island in the *CD44* transcriptional regulatory region is also often hypermethylated. This leads to transcriptional inactivation of the gene, as with *GSTP1*, and a resultant decrease in CD44 expression. CD44-negative cell lines, such as LNCaP, demonstrate hypermethylation of the promoter, whereas CD44-expressing cells do not exhibit this methylation. Examination of primary prostate cancer specimens confirms the increased presence of CpG hypermethylation when compared to normal tissues. Aberrant methylation has also been found at the endothelin B (*ETB*) receptor gene. Endothelin B is not expressed in human prostate cancer cell lines and shows decreased binding to endothelin-1 in prostate cancer tissues. The low ETB expression in prostate cancer was correlated with methylation of the CpG-island sequences in the *ETB* gene. Normal tissues were unmethylated at the *ETB* transcriptional regulatory region, whereas treatment of cancer cell lines with a demethylating agent induced *ETB* mRNA expression. Thus, CpG-island methylation and transcriptional silencing appear to be important in many genes involved in prostate cancer.

11
Androgen Receptor

The AR mediates the actions of androgens in both the normal and abnormal prostate cell. This, combined with the necessity of androgens in prostate carcinogenesis and the inevitable development of androgen insensitivity with continued androgen deprivation, has focused much effort into examining the role of AR in early and late prostate cancer. Inherited susceptibility to prostate cancer may be transmitted by AR polymorphisms. Two microsatellite repeats, CAG and GGN, are located within exon 1 of the *AR* gene. Whereas expansion of the CAG repeats from 40 to 62 is associated with spinal and bulbar muscular atrophy (Kennedy's syndrome), less than 19 CAG repeats are associated with a 1.52 relative risk for prostate cancer ($p = .04$). In addition, men with shorter CAG microsatellites were at higher risk for metastatic disease. A 3% decrease in prostate cancer risk with each additional CAG repeat has been noted, and various studies have found similar results. However, variations in the lengths have not been consistently associated with altered AR function. Although patients with Kennedy's syndrome have been reported to possess reduced androgen binding capacity, other investigators have found normal hormone binding, transactivation, and transrepression potential in these men. The frequency of CAG repeat lengths differs among the ethnic groups. Shorter repeats are more common in black men, who have a higher incidence of prostate cancer. Conversely, more CAG repeats are found in populations at lower risk such as Asians and Whites. This polymorphism could, in part, explain the ethnic differences in prostate cancer incidence. Length of the GGN repeat has been inconsistently associated with potential for prostate cancer development. Some have found any deviation from a repeat length of 16 to impart a higher risk (odds ratio 1.18), whereas others report lengths less than 16 to be a risk factor. No significant differences were found between cancer cases and controls with respect to GGN repeat length. The observed gain of chromosome Xq in hormone-refractory prostate cancer suggested involvement of the AR, located at chromosome Xq12. Amplification of AR was detected in 30% of recurrent cancers, but none of the primary tumors, in patients receiving hormonal therapy. *AR* gene amplification leads to increased mRNA levels, and high AR expression is seen in androgen-independent tumors. Almost all primary and metastatic lesions express AR, however, prior to endocrine treatment. Thus, mechanisms other than loss of AR are involved in progression to a metastatic or androgen-independent state. Indeed, prior androgen ablation may select for *AR* gene amplification. Significantly longer median survival has been found in patients with *AR* amplification than those without it. *AR* mutations are relatively infrequent, ranging from 0 to 41%. This further suggests that the development of prostate cancer occurs in the presence of normal AR expression. Moreover, the AR pathway likely remains important in advanced and hormone-refractory cancers. Often, mutations are found in metastatic but not primary tumors. *AR* mutations have been found in half of the hormone-independent, metastatic lesions, all of which were clustered in the steroid-binding domain (exons 4 to 8). Changes in this area may lead to loss of repression of AR transactivation in the absence of androgen or increased affinity to steroids such as estrogen and progesterone. Over 50 *AR* mutations have been identified and

can occur in the amino-terminal domain (exon 1), DNA-binding domain (exons 2 to 3), and hinge region (exon 4). Mutations in the AR and overexpression may provide the cells with a means of continued growth despite low androgen conditions, a sensitization of the AR pathway. Other means of sensitizing the pathway include activation of AR in a ligand-independent manner by growth factors and cytokines or amplification of coactivators. Finally, some prostate cancer cells have bypassed the AR pathway altogether. A recent study demonstrated the important roles of AR-associated protein 55 (dARA55) coregulator in the AR-mediated growth of prostate cancer and thus provided evidence that AR function could be suppressed without mutation or change in AR itself.

Overall, the AR plays an important role in prostate cancer recurrence. *AR* amplification may lead to continued stimulation with low, residual androgens, whereas *AR* mutations can alter receptor specificity. New reports document an important role of AR coactivators in bypassing traditional methods of androgen ablation. A better understanding of the mechanisms of AR-dependent and AR-independent growth will improve current and target future methods of androgen manipulation in prostate cancer. Polymorphisms in other genes of the androgen-signaling cascade may contribute to the racial and ethnic differences in prostate cancer incidence and biologic behavior. 3β-hydroxysteroid dehydrogenase (type 2) (*HSD3B2)* is involved in the catabolism of dihydrotestosterone. Twenty-five alleles of the (TG)n(TA)n(CA)n dinucleotide repeat in the *HSD3B2* gene have been identified, with the 289-bp form being the most common. The shorter 275-bp allele was more common in Blacks, and longer alleles (281-bp, 302 to 340 bp) were more common in European-Americans and Asians. A similar polymorphism exists in the 3′ untranslated region of the 5α-reductase type 2 gene (*SRD5A2*), whose product converts testosterone to dihydrotestosterone. The most common allele is the (TA)0 form, without TA repeats, found in a majority of men, whereas the two other alleles are less frequent ((TA)9, (TA)18). Blacks possessed the (TA)18 allele in 18% of cases studied; this allele was not found in Asian or White populations. In addition to reporting the epidemologic finding of increased risk of cancer in Black and Hispanic men with the A49T missense substitution in *SRD5A2*, one study found high enzymatic activity of the A49T variant in an *in vitro*, mammalian system. It is thought that the *HSD3B2* and *SRD5A2* polymorphisms result in increased prostatic levels of dihydrotestosterone and therefore increased risks of prostate cancer. Additional functional and *in vivo* studies are necessary to substantiate this hypothesis.

12 Conclusions

A wide variety of genetic alterations are potentially involved in prostate carcinogenesis. An improved understanding of the molecular basis will improve screening of patients at high risk for tumor, allow more accurate assessment of prognosis prior to and after initial therapy, and direct research toward novel and rational treatment strategies.

Keywords

Cancer Stem Cell
A cell within a tumor that possesses the ability to self-renew and is responsible for maintaining the growth of the tumor; this cell population is the only cell population within a tumor that has the ability to form a new tumor and can produce progeny of multiple phenotypes.

Self-renewal
The process by which, upon cell division, at least one of the daughter cells retains the multipotent capacity of the parent cell.

Tumorigenic Cell
A tumor cell capable of self-renewal and of forming a new tumor.

Researchers have made stunning advances over the last fifty years in characterizing the oncogenic mutations that lead to cancer. However, we are just beginning to understand the complex consequences of these mutations and how they result in neoplastic transformation at the cellular level. Most cancers arise in tissues that contain a stem cell population, such as gut, breast, prostate, lung, and bone marrow. Stem cells are defined by three critical properties: the ability to divide and give rise to a new stem cell (self-renewal), the ability to give rise to the differentiated cells of an organ, and the genetic constraints on expansion of the cell population. It is known that cancer results from the accumulation of mutations in a single target cell, sometimes over a period of many years. Since stem cells are the only long-lived cells in most tissues, this suggests that they are the cells in which early mutations leading to cancer accumulate. Additionally, stem cells are the only normal cells that share cancer cells' intrinsic ability to self-renew. Taken together, these two facts suggest that, in some cases, stem cells may be the target cells for neoplastic transformation.

Presently, therapeutic targets are selected on the basis of the assumption that all of the cancer cells within a particular tumor are equivalent in that they are all capable of driving tumorigenesis and metastasis. New data suggests that, in at least some cancers, a small, phenotypically distinct subset of the cancer cells (tumorigenic cells, or cancer stem cells) has the exclusive ability to form tumors. The rest of the cells, which form the bulk of the tumor, are unable to self-renew or sustain tumorigenesis. Tumorigenic and nontumorigenic cancer cells can be identified on the basis of cell surface-marker expression, utilizing the same tools used in normal stem cell biology. This suggests that therapies could be made more effective by targeting the tumorigenic cell population. The ability to identify tumorigenic cancer cells should therefore allow the identification of new diagnostic markers and therapeutic targets, better evaluation of candidate therapeutics, and more accurate determination of therapeutic efficacy.

1 Introduction

Most tissues in which common cancers arise contain a subpopulation of proliferating cells that are responsible for replenishing the short-lived mature cells as they undergo apoptosis or are otherwise damaged. Cell maturation is arranged in a hierarchy in which this rare subpopulation of stem cells give rise to progenitor cells and eventually mature cells; the stem cell pool replenishes itself through a process called *self-renewal*.

Recent discoveries indicated that it is likely that the tumors contain a minority ''cancer stem cell'' population with indefinite proliferative potential that drives the growth and metastasis of tumors. Furthermore, emerging evidence suggests that similar molecular mechanisms regulate self-renewal in normal stem cells and their malignant counterparts. If this is true, a more complete understanding of the cellular biology of the tissues in which cancers arise, and specifically of the stem cells residing in those tissues, could provide new insights into cancer biology. Certain aspects of stem cell biology apply to cancer. First, both normal stem cells and cancer stem cells undergo self-renewal – a property that separates them from the bulk of normal tissue cells and the bulk of tumor cells, respectively. Additionally, it is quite likely that mutations that lead to cancer accumulate in normal stem cells since they are the only long-lived cells in many tissues.

2 Evidence for Cancer Stem Cells

2.1 Viewing a Tumor as an Abnormal Organ

Cancers consist of phenotypically heterogeneous populations of cancer cells. These phenotypically distinct cell populations could arise, in part, from sequential mutations occurring because of either genetic instability and/or environmental factors. Another possible source of this heterogeneity becomes apparent if one views a tumor as an aberrant organ containing a tumorigenic (stem cell) population that

drives tumor growth. These tumorigenic cells would have acquired oncogenic mutations that result in deregulated self-renewal, but their phenotypically diverse progeny would still be differentiated and lack the ability to self-renew. Several lines of evidence suggest that this model accounts for some of the cellular heterogeneity seen in tumors, although genetic instability and environmental factors undoubtedly contribute to the variability in phenotypes of cancer cells in a particular tumor. It is well documented that many types of cancer contain heterogeneous populations of cells, which variably express differentiation markers that reflect the tissue or origin, as well as cancer cells that have an immature morphology. Examples of this observation include the variable expression of milk proteins by some breast cancers and the variable expression of myeloid and/or lymphoid markers in chronic myelogeous leukemia (CML) and acute myelogenous leukemia (AML). By contrast, in some tumors, specifically in mature germ cell teratomas, only a minority of the cancer cells express immature cell markers such as α-fetoprotein. Because the terminally differentiated cells that form the teeth and hair in germ cell teratomas are unlikely to be able to proliferate and form new tumors, these data are consistent with the notion that the minority population of α-fetoprotein expressing cancer cells might have the exclusive ability to form new tumors consisting of more tumorigenic cells as well as the phenotypically diverse populations of abnormally differentiated cells lacking the ability to self-renew. If this proved to be true, these cells could be considered to be cancer stem cells.

The evidence suggesting that cancer is a disease of aberrant differentiation, proliferation, and self-renewal makes it plausible to view tumors as abnormal organs; in this context, the principles of stem cell biology can be applied to better understand the biology of these diseases. It has been shown in both hematopoietic malignancies and solid cancers that only a subset of cancer cells are clonogenic when placed in tissue culture or injected into immunodeficient mice. For example, only 0.01 to 1% of the mouse myeloma cells formed colonies in *in vitro* colony-forming assays. Similarly, only 1 to 4% of leukemic cells formed spleen colonies when transplanted into mice. This trend was demonstrated in solid cancers as well, with only 0.02 to 0.1% of ovarian cancer or lung cancer cells forming colonies in soft agar. Since only a minority of normal bone marrow cells were clonogenic, the clonogenic cancer cells were initially described as cancer stem cells; this implied that only a distinct population of cancer cells were able to proliferate extensively in these assays. However, an alternative explanation was that all cancer cells have the intrinsic ability to proliferate extensively, but only a small minority of cells do so in a particular assay.

2.2 Recent Evidence for AML and Breast Cancer Stem Cells

Proving that a phenotypically distinct population of cancer cells is responsible for perpetuating the disease would require isolating different populations of cancer cells and demonstrating that one or more groups were enriched for the ability to initiate the disease while other populations lacked this ability. This was first shown in AML when it was shown that a leukemia tumor-initiating subpopulation of cells could be prospectively identified and purified from multiple patients' bone marrows. In most cases of AML,

the minority population of $CD34^{+}CD38^{-}$ cells was the only group of cells capable of establishing human AML in the bone marrow of Nonobese Diabetic Severe Combined Immuno-deficiency (NOD/SCID) mice. Within this population are also $Thy1^{+}$ $CD34^{+}CD38^{-}$ normal hematopoietic stem cells (HSCs). Since leukemia-initiating cells lack the Thy1 expression characteristic of normal HSCs, it is likely that while the early mutations occurred in the HSC, the final transforming mutations occurred in early downstream progenitors lacking Thy1 expression. An alternative explanation is that Thy1 expression could have been lost as a consequence of neoplastic transformation.

Tumorigenic and nontumorigenic subsets of cancer cells have recently been isolated from human breast cancer tumors, providing the first conclusive evidence for cancer stem cells in solid tumors. Using a model for human breast cancer similar to that used for AML, cells were isolated, sorted by surface marker expression using flow cytometry, and grown in immunocompromised mice, as shown in Fig. 1. A minority population of breast cancer cells was identified in these tumors, which was exclusive in its ability to form new tumors. Tumorigenic cells could be distinguished from nontumorigenic cancer cells based upon surface-marker expression that was consistent from patient to patient. In eight out of nine patients, tumorigenic cells could be prospectively identified and isolated as $CD44^{+}CD24^{-/low}Lineage^{-}$ cells. In a subset of these tumors, Epithelial Specific Antigen (ESA) provided further enrichment of the tumorigenic population. Limiting dilution assays

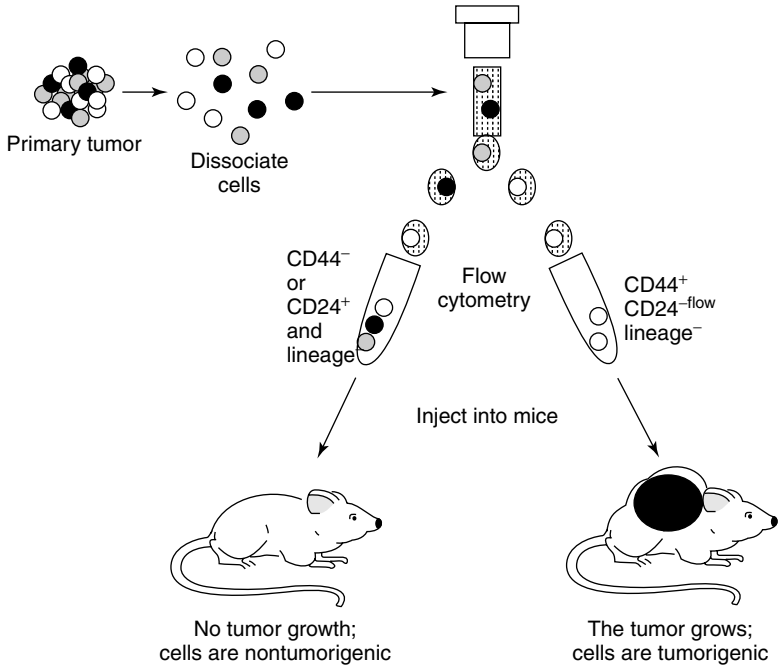

Fig. 1 Identification of breast cancer tumorigenic cells.

demonstrated that as few as one hundred $CD44^+CD24^{-/low}Lineage^-$ cells were able to form tumors, while tens of thousands of cancer cells from outside this population failed to form tumors in NOD/SCID mice, as shown in Fig. 1. These tumorigenic cells could be serially passaged, and each time cells within this population generated new tumors containing additional $CD44^+CD24^{-/low}Lineage^-$ tumorigenic cells. Additionally, phenotypically mixed populations of nontumorigenic cancer cells were produced that composed the bulk of the tumor. Importantly, their phenotypic distribution resembled that of the original tumor. These data demonstrate the presence of a hierarchy of cells within a breast cancer tumor in which only a fraction of the cells have the ability to proliferate extensively, while other cells have only a limited proliferative potential, suggesting that the tumorigenic cells can both self-renew as well as differentiate. The phenotype of the tumorigenic breast cancer cells may be similar to normal breast stem or progenitor cells, since early multipotent epithelial progenitor cells have been reported to express both ESA and CD44. While this would be consistent with the similarities observed between normal HSCs and AML tumor-initiating cells, definitive proof will depend upon the characterization of the differentiation hierarchy of breast tissue.

The $CD44^+CD24^{-/low}Lineage^-$ tumorigenic breast cancer cells and the $CD34^+CD38^-$ leukemia-initiating cells share with normal stem cells the ability to proliferate extensively, as well as to give rise to cells of diverse phenotypes with reduced developmental or proliferative potential. The extensive proliferative potential of tumorigenic cancer cells contrasts with the bulk of the cancer cells, which lack the ability to form detectable tumors and form smaller colonies *in vitro*. Thus, both tumorigenic breast cancer cells and leukemia-initiating cells from most tumors appear to exhibit the properties of cancer stem cells. However, before these cells can definitively be called cancer stem cells, new assays will be necessary to demonstrate that a single transplanted cell gives rise to all of the diverse populations of cancer cells within a tumor.

Cancer stem cells share many key properties with normal stem cells, including the ability to self-renew. In addition, normal stem cells are likely to be the cells in which oncogenic mutations accumulate and in some cases may be the target cells for neoplastic transformation. Appreciating the implications of the discovery of cancer stem cells for the diagnosis and treatment of cancer consequently depends upon understanding the key properties of stem cells, the genetic regulation of these properties, and how cells can be targeted for neoplastic transformation.

3 Properties of Normal Stem Cells

3.1 The Hematopoietic Stem Cell and its Properties

The accessibility of the hematopoietic system to study has made the HSC the most studied and best understood somatic stem cell population; consequently, it serves as a model for stem cells from other tissues. Hematopoiesis is a tightly regulated process in which a pool of HSCs, through a series of divisions and immature progenitors, eventually gives rise to the mature lymphohematopoietic system consisting of the formed blood

elements, for example, red blood cells, platelets, granulocytes, macrophages, and B- and T-lymphocytes. These cells are responsible for oxygenation, prevention of bleeding, infection prevention, and immunity, respectively. The HSC pool has three fundamental properties in the adult. First, self-renewal allows the maintenance of the stem cell pool. Self-renewal is not analagous to proliferation; self-renewal is a cell division in which one or both the daughter cells remain undifferentiated and retain the ability to give rise to another stem cell as well as to differentiated progeny. Proliferation does not require either daughter cell to be a stem cell, nor does it retain the ability to give rise to multiple lineages. Second, they must differentiate in order to maintain a genetically regulated pool of mature cells under homeostatis, and to produce increased numbers of a particular lineage in response to environmental stresses, including bleeding or infection. Third, the total number of HSCs must be under strict genetic regulation. Since only stem cells comprise a rare subset of cells within a tissue, they must be isolated in order to study their biological, molecular, and biochemical properties. Although it is thought that they give rise to most tissues, stem cells have been rigorously identified and purified only from a handful. The stem cells that give rise to the lymphohematopoietic system, called *hematopoietic stem cells*, were one of the first stem cell populations characterized and have been isolated from both mice and humans. The utility of stem cell biology in the clinic has already been demonstrated in cancer therapy with their extensive use for bone marrow transplantation to regenerate the hematolymphoid system following myeloablative protocols.

3.2 The Hierarchy of the Hematopoietic System

The multipotent cells of the hematopoietic system constitute only 0.05% of mouse bone marrow cells and are heterogeneous in their ability to self-renew. The lymphohematopoietic system consists of a hierarchy in which long-term HSCs give rise to short-term HSCs, which in turn give rise to multipotent progenitors; only long-term and short-term HSCs have detectable self-renewal potential. Cells become more mitotically active as they progress through the differentiation hierarchy, but lose the ability to self-renew. Only long-term HSCs can replenish the full hematopoietic system for the lifetime of an animal; short-term HSCs and multipotent progenitors reconstitute lethally irradiated mice for less than eight weeks.

3.3 Self-renewal: The Defining Property of Stem Cells

While the functional and phenotypic properties of mouse and human HSCs have been extensively studied, our understanding of the fundamental property defining stem cells, self-renewal, is minimal. HSCs differentiate when exposed to combinations of growth factors that can induce extensive proliferation in long-term cultures, complicating *in vitro* studies of self-renewal. Despite recent progress in identifying culture conditions that maintain HSC activity in culture for a limited period of time, it has proven exceedingly difficult to identify tissue culture conditions that allow a significant and prolonged expansion of progenitors while maintaining a transplantable HSC population.

4
Genetic Regulation of Self-renewal in Normal Stem Cells and Cancer Cells

4.1
Tissue and Tumor Growth: A Balancing Act

The maintenance and composition of a tissue or tumor is determined by the balance of proliferation and cell death. It is therefore logical that many of the mutations that are known to drive tumor expansion and progression regulate either cell proliferation or survival. For example, the prevention of apoptosis by enforced expression of the oncogene *BCL-2* promotes the development of lymphoma as well as results in an increased number of HSCs *in vivo*, suggesting that cell death plays a role in the regulation of HSC homeostasis. Inhibition of intrinsic cell death pathways has been further implicated in tumorigenesis by the observation that the progression to experimental AML in a mouse model requires at least three, and likely four independent events. Proto-oncogenes that drive proliferation of tumor cells, such as *c-myb* and *c-myc*, are also essential for HSC development and proliferation.

4.2
Multiple Oncogenes Implicated in Self-renewal

Self-renewal is critical for the maintenance of both normal and cancer stem cell populations. In a normal tissue, stem cell numbers are under strict genetic regulation, resulting in the maintenance of a stable stem cell pool. Cancer stem cells, however, have escaped this homeostatic regulation. Not only is the number of stem cells constantly expanding but they are also proliferating without the normal constraints on their expansion. This results in the relentless growth of the tumor. Since cancer cells and normal stem cells share the ability to self-renew, it is not surprising that a number of genes classically associated with cancer have recently been implicated in normal stem cell development.

In combination with other growth factors, Sonic Hedgehog (Shh) signaling was implicated in the regulation of self-renewal when it was found that cell populations highly enriched for human HSCs exhibited increased self-renewal in response to Shh stimulation *in vitro*. Mice that are deficient in *tal-1/SCL*, which is involved in some cases of human acute leukemia, lack embryonic hematopoiesis. This suggests that *tal-1/SCL* is required either to initiate hematopoiesis for the maintenance of the earliest definitive blood cells, or for the decision to form blood cells downstream of embryonic HSCs. Members of the Hox family have likewise been implicated in human leukemia. Enforced expression of *HoxB4* can affect stem cell functions. One of the major targets of the p53 tumor suppressor gene, $p21^{cip1}$, is necessary for HSCs to repopulate lethally irradiated recipients. Failure at serial transfer could result from exhaustion of the stem cell pool, loss of telomeres, or loss of transplantability. The *bmi-1* gene, which cooperates with *c-myc* in mice to induce lymphoma, is required for the maintenance of both adult HSCs and leukemia cells. Taken together, this body of evidence suggests that the same pathways involved in stem cell fate decisions and the ability of stem cells to self-renew are also involved in malignant transformation.

The Wnt/β-catenin and Notch pathways, which have been implicated in cancer in both mice and humans, may have critical functions in the self-renewal of both normal and cancer stem cells. The Notch

family of receptors was first identified in *Drosophila* and has been implicated in both development and differentiation. In *Caenorhabditis elegans*, Notch plays a role self-renewal of germ cells. In higher animals, Notch plays a critical role in the fate determination of neural crest stem cells. Specifically, transient Notch activation induces an irreversible switch from neurogenesis to gliogenesis. In cultured HSCs, Notch activation using either of the Notch ligands (Jaged-1 or Delta) transiently increased the number of primitive progenitors; this result proved true in *in vivo* studies as well. This suggests that Notch activation promotes either the maintenance of progenitor cell multipotentiality or the maintenance of self-renewal in HSCs. The Notch pathway was implicated in cancer when it was determined that the mouse oncogene *int-3* was a truncated Notch-4. However, the role for Notch in *de novo* human cancer is complex and incompletely understood. It is known that some members of the Notch signaling family are expressed in cancers of epithelial origin, and activation of Notch by chromosomal translocation is involved in some cases of leukemia. Microarray analysis has demonstrated overexpression by tumor cells. Specifically, overexpression of Notch-1 leads to growth arrest of a small cell lung cancer cell line, while inhibition of Notch-1 signals can induce leukemia cell lines to undergo apoptosis. Elegant work by Miele and colleagues showed that activation of Notch-1 signaling maintains the neoplastic phenotype in ras-transformed human cells. They also found that in *de novo* cancers, cells with an activating ras-mutation also demonstrated increased expression of Notch-1 and Notch-4. Additionally, a truncated Notch-4 mRNA is expressed by some breast cancer cell lines.

In addition to the Notch pathway, Wnt/β-catenin signaling has also been implicated as a major player in the malignant transformation and self-renewal of normal stem cells. The Wnt pathway was first implicated in cancer when it was discovered that some murine mammary tumors were the result of mouse mammary tumor virus proviral insertion into the *Wnt-1* gene, causing deregulated expression of the locus. Subsequently, it has been shown that Wnt proteins play a central role in pattern formation during embryogenesis as well as in some adult tissues. The Wnts are a large family of highly hydrophobic secreted proteins that signal through their cognate receptors, members of the frizzled and low-density lipoprotein receptor-related protein families. Activation of these receptors results in the cytoplasmic and nuclear stabilization of β-catenin by blocking its degradation. In the absence of receptor activation, β-catenin is marked for degradation by ubiquitination by a complex consisting of the adenomatous *polyposis coli* (APC), axin, and glycogen synthase-3β proteins. Activation of Wnt/β-catenin signaling by Wnt proteins in HSCs *in vitro* or by expression of a constitutively active β-catenin in HSCs expands the pool of early progenitor cells and enriches normal transplantable HSCs in tissue culture and *in vivo*. Inhibition of Wnt/β-catenin by ectopic expression of axin (which promotes β-catenin degradation) leads to the inhibition of stem cell proliferation both *in vitro* and *in vivo*. Additional studies implicate the Wnt/β-catenin pathway in the maintenance of stem cell or progenitor cell self-renewal in other tissues as well. Specifically, the level of β-catenin within a particular keratinocyte directly correlates with its proliferative capacity. Additionally,

enforced expression of an activated β-catenin increased the ability of epidermal stem cells to self-renew and decreased their ability to differentiate. In the intestinal epithelium, it has been observed that β-catenin levels are highest in the bottom of the crypts (where the epithelial stem cells are thought to reside), and decrease in a gradient as cells differentiate and move up and out of the crypt. Knockout mice for TCF-4, one of the transcription factors that is activated when bound to β-catenin, soon exhaust their undifferentiated crypt epithelial progenitor cells; this further suggests that Wnt signaling is involved in the self-renewal of epithelial stem cells in the intestine.

Activation of the Wnt/β-catenin can take place by one of several mechanisms. In colon cancer, inactivation of the β-catenin protein degradation pathway, most frequently by mutation of APC, is common. Alternatively, elevated expression of *Wnt* genes in some epithelial cancers suggests that activation of β-catenin might sometimes be secondary to ligand activation. There is now evidence that constitutive activation of the Wnt/β-catenin pathway may confer upon cancer cells some of the key properties of cancer stem cells. Inhibition of β-catenin/TCF-4 signaling in a colon cancer cell line induced the expression of the cell cycle inhibitor $p21^{cip-1}$ and induced the cells to stop proliferating and to acquire a more differentiated phenotype. Additionally, enforced expression of the proto-oncogene *c-myc*, which is activated by β-catenin through TCF-4, inhibited the expression of $p21^{cip-1}$ and allowed the colon cancer cells to proliferate when β-catenin/TCF-4 signaling was blocked. This further enforced the notion that *c-myc* is a key *Wnt* signaling target gene in the regulation of cell proliferation and differentiation.

4.3 Possibility of a Common Self-renewal Pathway among Multiple Cell Types

The implication that genes such as *Notch*, *Wnt*, *c-myc*, and *Shh* all play roles in the regulation of not only HSC self-renewal, but also in the self-renewal of stem cells from multiple tissues, suggests that there may be a common set of self-renewal pathways utilized both in normal stem cells and possibly in cancer stem cells. It is clear that identifying the molecular mechanisms by which these pathways produce their biological effects, as well as determining whether these pathways interact to regulate the self-renewal of normal stem cells and cancer stem cells, could have profound importance in our understanding of cancer biology and our ability to effectively treat the disease.

5 Target Cells for Malignant Transformation

5.1 Stem Cells as Targets for Malignant Transformation

It has been established that oncogenic mutations often target signaling pathways that regulate proliferation and self-renewal. This fact raises an interesting question: are stem cells, highly proliferative progenitor cells, or both, the target cells of neoplastic transformation? Theoretically, stem cells could be transformed by acquiring mutations that deregulate proliferation, while highly proliferative progenitors could be transformed by mutations conveying the ability to self-renew.

Several lines of evidence suggest that stem cells may play several key roles in the evolution of a cancer. First, multiple

mutations are necessary for a cell to become cancerous. Since both progenitor cells and mature cells have a very limited lifespan, it is unlikely that all of the mutations could occur during the life of these relatively short-lived cells. This evidence suggests that, in many cases, mutations accumulate in a stem cell. Second, the regulation of stem cell expansion and self-renewal is under strict genetic regulation by multiple genes. Unregulated expansion of the stem cell pool would therefore be analogous cancer. Third, most cancers arise in tissues that contain stem cells that have the intrinsic ability to self-renew. Cancer cells must overcome the tight genetic regulation restricting both self-renewal and proliferation. Since cancer cells must possess the ability to self-renew, it follows that stem cells (which could be transformed by altering only proliferative pathways) may more easily undergo malignant transformation than progenitor cells that lack this fundamental property and must therefore activate both proliferative and self-renewal pathways to become malignant. In the hematopoietic system, the only cells with self-renewal capability are HSCs and mature lymphocytes. The common blood cancers, acute leukemias, and lymphomas, may arise from the HSCs or lymphocytes, respectively. This may take place through the constitutive activation of mitogenic pathways associated with the proliferation of normal cells. Finally, while many cancers contain cells displaying aberrant expression of differentiation markers from their tissue of origin, germ cell cancers are the only cancers to produce differentiated cells from multiple tissues. For this reason, marker expression is routinely used to determine the tissue of origin in metastatic disease. If a differentiated cell were to be the origin of a cancer, it would be necessary for the cell to dedifferentiate exclusively along its parent lineage to produce expression of markers from multiple cell types within the tissue. However, if a somatic stem cell or early multipotent progenitor were transformed, the cell would already be genetically programmed to give rise to cells expressing markers of multiple lineages, but from only one tissue type, as is usually observed clinically. Since most identified oncogenic mutations are involved in the regulation of proliferation and self-renewal and not lineage commitment, the latter hypothesis seems more likely.

5.2 Progenitor Cells as Targets for Malignant Transformation

Although evidence supports the hypothesis that stem cells are frequently the target of mutations that lead to malignant transformation, it is likely that progenitor cells, possibly arising from mutated stem cells, may be transformed by subsequent genetic events that confer immortality and/or self-renewal potential to these normally non-self-renewing cells. In CML patients, the BCR-ABL mutation is present in both normal HSCs and leukemic stem cells. In otherwise normal hematopoietic cells, the BCR-ABL mRNA is expressed solely by the progenitor cells. BCR-ABL expression targeted to myeloid progenitor cells by the hMRP-8 promoter in a transgenic mouse model of CML resulted in CML-like disease in a subset of the mice. Furthermore, when hMRP8p210$^{BCR/ABL}$ mice were crossed with hMRP8bcl-2 mice (which possessed myeloid progenitors resistant to apoptosis), a portion of the mutant mice developed a disease resembling AML. Although expression of transforming genes was targeted to early progenitor cells and not the HSCs, the

morphology of the leukemia cells and clinical course resembled human CML and AML in the hMRP8p210$^{BCR/ABL}$ mice and the hMRP8p210$^{BCR/ABL}$/hMRP8bcl-2 mice, respectively.

In a mouse model of high grade glioblastoma, enforced expression of the epidermal growth factor receptor (EGF-R) in enriched populations of either Ink4a/Arf null neuronal stem cells or Ink4a/Arf null astrocytes led to malignant glioblastomas when the cells were injected orthotopically into mice. Notably, in the majority of cases the transformed astrocytes appeared to acquire an immature phenotype in the brains of the mice, suggesting that there was ''dedifferentiation.'' However, such dedifferentiation has never been conclusively demonstrated. There are two other possible explanations for these results. First, since it is unlikely that the cell culture achieved 100% purity, it is possible that the astrocyte tissue culture cells could have contained a population of neuronal stem cells that were transformed; these stem cells could then have been responsible for generating the tumors. In this case, the immature appearance of the cells could reflect a deregulated expansion of the stem cell pool or early progenitor pool, the result of which would be the overt glioblastoma that was observed. Second, it is possible that the tissue culture conditions, in conjunction with the enforcement of EGF-R expression, could have caused the dedifferentiation of the astrocytes *in vitro*, and that unless the astrocytes were grown in tissue culture first they could not later give rise to glioblastomas in an animal.

The human and mouse observations support the notion that oncogenic mutations accumulate in the stem cells. Expression of the mutated gene by progenitors downstream of the stem cells, or an additional mutation in a short-lived progenitor cell, can lead to neoplastic transformation. These observations have implications for targeted therapies.

It is possible that only a minority of the mice, whose progenitors express BCR-ABL, develop leukemia because the progenitors must acquire an additional mutation that causes deregulated self-renewal. There are two lines of evidence that support this hypothesis. First, expression of *bmi-1* is necessary for the self-renewal of adult HSCs; blast cells of patients with AML express large amounts of this protein. While expression of *HoxA9* and *Meis1* induces transplantable AML in normal mice, expression of these genes in the absence of Bmi-1 does not. This suggests that, in at least some leukemic blasts, a mutation activating *bmi-1* must take place in order to confer self-renewal capability onto the blast cells. Second, deregulated β-catenin signaling occurs in many *de novo* human cancers and causes cancer in transgenic mouse models. Because expression of a constitutively active β-catenin can promote the self-renewal of normal HSCs and stem cells from other tissues, it is possible that its activation promotes self-renewal of cancer cells in these tissues as well. On the basis of these data, it is clear that achieving an understanding of the molecular regulation of self-renewal in both normal stem cells and cancer cells could lead to more effective therapies for cancer.

5.3 Targets for Malignant Transformation in Hematopoietic Malignancies

The systems in which the target cells for transformation are best understood are hematopoietic malignancies; this is because the developmental hierarchy of the

blood is well understood. When this knowledge is combined with analysis of oncogenic mutations, it can be inferred from which cell type along the differentiation lineage the cancer arose. One of the most frequent mutations in AML is the t(8 : 21) mutation, which results in the expression of a chimeric AML-ETO transcript in the leukemic cells. HSCs isolated from patients in clinical remission were found to express chimeric AML-1-ETO transcript up to 90% of the time. When analyzed using *in vitro* assays, these HSCs gave rise to normal progeny, thus demonstrating that the mutation was present in phenotypically normal stem cells. In these patients, the $Thy1^-$ subset of $CD34^+CD38^-$ Lin^- cells gave rise to leukemic colonies *in vitro*. These cells could represent HSCs that lost Thy1 expression, or downstream multipotent progenitors that have gained the ability to self-renewal. Collectively, these observations support the idea that mutations accumulate in stem cells, and either subsequent mutations in stem cell progeny or selective activation in downstream progenitors results in overt leukemia.

6
Implications of Cancer Stem Cells for the Diagnosis and Treatment of Cancer

6.1
Cancer Stem Cells Would Explain Several Conundrums of Cancer Biology

Although the NOD/SCID mouse model provides compelling evidence in support of the cancer stem cell model, the ultimate confirmation of this hypothesis will require proof in humans. If this model can be confirmed in humans, however, it will have profound implications for the diagnosis and treatment of cancer. Several conundrums of cancer biology would be explained if it were conclusively demonstrated that, in most tumors, only a small population of cancer cells has the ability to self-renew while other populations of cancer cells have only a limited ability to proliferate. For example, for many years it has been recognized that disseminated cytokeratin-positive breast cancer cells can be detected in the bone marrow of patients that never relapse. One possible explanation of this observation is that the cancer cells lie dormant until some unknown event triggers them to renew proliferation. An alternative explanation is that the disseminated cancer cells in this group of patients arose from the spread of nontumorigenic cells, and only when cancer stem cells disseminate and subsequently self-renew, will metastatic tumors form. Thus, the development of diagnostic reagents that allow cancer stem cells to be identified may have prognostic significance for patients with breast cancer.

6.2
Tumor Relapse Might Result from a Failure to Target Cancer Stem Cells

A frustrating clinical observation is that in most solid cancers such as breast cancers, chemotherapy can frequently shrink tumors, but in most patients the tumors rapidly recur and there is only a small increase in patient survival. Most of the present cancer therapeutic agents have been developed for their ability to shrink a tumor; essentially, all of the phenotypically diverse cancer cells are treated as if they possess the ability to significantly contribute to the growth and maintenance of the tumor, as shown in Fig.2a. However, the failure of oncogenic mutations to confer unto all breast cancer

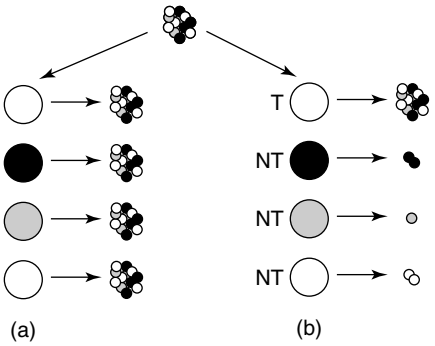

Fig. 2 (a) Therapies are currently evaluated assuming all cancer cells are equivalently tumorigenic. (b) The cancer stem cell model says only a distinct subpopulation drives tumorigenesis. Symbols: T = tumorigenic, NT = nontumorigenic.

and leukemia cells the ability to form new tumors or proliferate extensively underscores the fact that the effects of oncogenic mutations are not equivalent in all cancer cells, as shown in B in Fig 2. If only a minority of the cancer cells are tumorigenic and therefore responsible for driving tumor growth and metastasis, then tumor shrinkage must primarily reflect the elimination of the bulk population of nontumorigenic cells. If a substantial number of tumor stem cells were spared by the therapy, then the tumors would regenerate from these cells. The clinical observation that many patients treated with chemotherapy initially realize tumor shrinkage but then experience relapse at sites of prior disease, supports this model.

6.3 Cancer Stem Cells Might Be More Resistant to Chemotherapy

The similarities between normal stem cells and AML tumor-initiating cells suggest that they might share additional clinically significant parallels. For instance, compared to their differentiated progeny, normal HSCs express high levels of genes that make them more resistant to cytotoxic agents, including both antiapoptotic members of the *BCL-2* family and members of the ABC transporter family that pump many drugs out of the cell. If the same is true for cancer stem cells, then these cells may be significantly more resistant to cytotoxic agents than their nontumorigenic progeny. In support of this notion, while the chemotherapeutic agent cytosine arabinoside very efficiently killed leukemic blast cells isolated from many patients, it selectively spared the leukemia-initiating cells. This observation suggests that the effect of a particular therapeutic agent on the cancer stem cell population must be taken into account when evaluating its therapeutic efficacy.

6.4 Identification of Cancer Stem Cells Might Lead to Better Drug Selection

The fact that therapeutic agents are currently selected on the basis of their ability to rapidly shrink tumors suggests that agents that selectively target the cancer stem cells could be overlooked in screens to identify potential therapeutic agents. Initially, such agents would be expected to produce only a moderate decrease in tumor growth. However, elimination of the cancer stem cell population would eventually halt the spread of the tumor, possibly leaving a residual, benign mass. Perhaps, the best clinical evidence of this model occurs in patients with teratocarcinoma.

Platinum-based chemotherapy is curative in the majority of these patients; however, many patients are left with residual masses. The immature cancer cells have been eliminated by the chemotherapy, leaving only differentiated cancer cells, in a mature teratoma. Patients with mature teratomas rarely develop metastases; most are cured. This demonstrates that the elimination of the presumed stem cell population is sufficient for curing this solid cancer.

7 Future Implications of Cancer Stem Cells

The ability to prospectively identify cancer stem cells should have exciting implications for the development of new diagnostic tools and therapeutic agents. Currently, all of the cancer cells within a tumor are treated equivalently in their presumed ability to drive tumor growth, invade, and metastasize. The ability to identify these crucial cells will allow efforts to develop novel diagnostics and therapies focused on the cells responsible for the maintenance of the malignancy – the cancer stem cells. For example, immune therapy efforts to identify genes and proteins expressed by cancer cells presently use either whole tumors or all of the phenotypically diverse cells within a tumor. Since the cancer stem cells represent only a minority of the cancer cells in most tumors, it is nearly impossible to identify diagnostic markers or therapies that target these cells without their purification. However, directing expression analysis to enriched populations of cancer stem cells would allow the identification of novel diagnostic markers and therapeutic targets that can be exploited to more effectively diagnose and treat patients. This principle is illustrated by the observation that the BCR/ABL oncogene mRNA appears not to be expressed by HSCs that carry the mutation in their DNA; therefore, efforts to eradicate the cancer by targeting the BCR/ABL protein might fail to target the cancer stem cells.

As illustrated above for AML-initiating cells, the ability to prospectively identify cancer stem cells should also improve our ability to evaluate the curative potential of new therapeutic agents. Although cancer cell lines are useful for the evaluation of particular biochemical pathways, they have proven somewhat unreliable when used to predict the clinical efficacy of a particular therapeutic agent in patients. These cell lines are relatively homogeneous, and even tumors grown using these cell lines are homogeneous. This contrasts sharply with the phenotype of real tumors. However, tumors that are grown in the immunodeficient mouse model of human cancer appear to more closely recapitulate the phenotypic diversity of patients' original tumors, including the generation of both tumorigenic and nontumorigenic cells. This model might therefore more effectively predict the potential usefulness of a particular therapeutic agent. New agents could be tested for their ability to eliminate the tumorigenic (cancer stem cell) component of tumors from multiple patients, allowing the agents with the greatest curative potential to proceed to human clinical trials.

Keywords

Anomeric Structure
The steric configuration around the hemiacetal (reducing) carbon atom in carbohydrates.

Antennary Structure
The number and composition of the nonreducing oligosaccharide chains in glycoprotein glycans.

Capillary Electrophoresis
Chromatographic method that utilizes the interaction of eluant and analyte with the capillary wall to separate molecules in an electric field.

COSY
Correlated spectroscopy. A two-dimensional NMR technique that determines the through-bond connectivity of atoms.

Endoglycosidase
Enzyme that hydrolyzes internal glycosidic links in carbohydrate chains.

Exoglycosidase
Enzyme that hydrolyzes nonreducing terminal glycosidic links in carbohydrate chains.

FAB-MS
Fast atom bombardment mass spectrometry.

FFF
Field flow fractionation is a chromatographic technique that separates on the basis of molecular size.

GC
Gas–liquid chromatography (also abbreviated GLC). A method for separating volatile molecules.

Glycan
Oligosaccharide or polysaccharide chain present in carbohydrate-containing molecules.

HPAEC-PAD
High-performance anion-exchange chromatography with pulsed amperometric detection; an HPLC system developed for polyalcohols.

HPLC
High-performance liquid chromatography; a method for separating molecules in solution, often conducted at relatively high pressures.

ICUMSA
The International Commission for Uniform Methods of Sugar Analysis, c/o British Sugar plc, Technical Centre, Colney, Norwich, UK. Publishes standardized methods of food carbohydrate analysis at regular intervals.

Lectins
Proteins or glycoproteins of nonimmune origin that bind carbohydrates.

MALDI-TOF
Matrix-assisted laser-desorption ionization mass spectrometry.

MALLS
Multiangle laser light scattering is a technique for determining the molecular weight of polymers.

NMR
Nuclear magnetic resonance; a spectroscopic process for examining nuclear environments.

NOESY
Nuclear Overhauser effect spectroscopy. A two-dimensional NMR technique that determines the through-space relationship of atoms.

O-Glycoside
Compounds in which a sugar is linked to another molecule through its reducing group to form an acetal.

ROESY
Rotational nuclear Overhauser effect spectroscopy. A variation in the two-dimensional NMR NOESY technique that determines the through-space relationship of atoms. It is especially useful for cases in which NOESY signals are weak in spite of atoms being close.

SEC
Size-exclusion chromatography is a technique that separates on the basis of molecular size.

TLC
Thin-layer chromatography; a chromatographic system based on partition.

Carbohydrates form a complex family of molecules that necessitate a variety of analytical approaches. They are capable of forming a large number of distinct structures using relatively few units. In addition, the more complex carbohydrates are rarely found to exist as single structural entities; polymorphism is common, and often a given molecule is found as an assortment of closely related structures. These mixtures of complex structures give rise to analytical problems that are much more difficult to solve than those concerning protein analysis. Typical protocols involve isolation and purification, determination of the constituent carbohydrates, partial hydrolysis of polysaccharides or glycosaminoglycans or cleavage of the intact glycans from the protein or lipid moieties, and isolation and purification of these fragments. Chromatographic purification techniques are followed by mass spectrometry and/or NMR spectroscopy. Absolute molecular weights of larger molecules are determined by light scattering, but uncovering their conformation often requires the assistance of molecular dynamics. However difficult to obtain, a solid understanding of the structure and conformation of carbohydrates is required a our proper understanding of their biological roles.

1 Outlines of Methodology

1.1 Introduction

Carbohydrates, which form the most diverse of all the major groups of biological compounds, possess a wide variety of structural types with very different chemical and physical characteristics. They are formed from basic structures that commonly have a backbone of five or six carbon atoms and possess several alcohol groups and a hemiacetal or, more rarely, a hemiketal group. Less commonly found are carbohydrate units containing a nine-carbon backbone, whilst those with seven and eight carbons are only rarely found. In spite of the extraordinarily large number of isomers possible, only relatively few basic units (*monosaccharides*) are found as the basic building blocks of more complex molecules (Fig. 1). These units link in a number of ways between the monosaccharide units utilizing different hydroxyl groups and forming simple or complex structures. Different monosaccharides may be joined together in an ordered or apparently random manner to form a mainly homogeneous or heterogeneous family of structural entities, termed *glycans*. Again, only a limited subgroup of the possible isomers is generally found. For example, more than 50 different D-glucose dimers and more than 1000 trimers are possible, although only 5 dimers and 2 trimers are commonly encountered. These carbohydrate moieties may also be linked to proteins or lipids in glycoproteins, proteoglycans,

and glycolipids. As these glycans are not directly genetically coded, but their organization depends on the sequential action of enzymes, all such carbohydrates are commonly found to be somewhat heterogeneous. This may be a microheterogeneity as evident in glycoprotein glycans in which most of the structure remains constant, but a variety of structures exist due to missing residues at the molecule's periphery. Alternatively, there may be sequence and linkage heterogeneity, as found in heteropolysaccharides, or molecular weight heterogeneity, as is common in homopolysaccharides.

The principal classes of carbohydrates are listed in Table 1, together with the most commonly encountered analytical methods. Since glycoproteins form the class of carbohydrates containing material that is of major importance to cell and molecular biologists, this article concentrates on methods for their analysis. The analytical problems surrounding the carbohydrates are clearly orders of magnitude more difficult than that of protein analysis; indeed it is apparent that for many polysaccharides no two molecules are likely to be identical and the concept of "structure" must be investigated and interpreted differently from that for proteins with more emphasis on the statistical relevance. There is a further level of complexity if the conformation of the carbohydrates in solution is sought as, in contrast to protein structures, these are generally not fixed but fluctuate widely and may change irreversibly during isolation or with apparently minor changes in the temperature, solvent, pH, ionic strength, concentration, or co-solutes.

Tab. 1 The important analytical methods for carbohydrates.

Carbohydrate	***Usual analytical method(s)***
Monosaccharides and disaccharides	
In syrups	ICUMSA empirical methods
In food	Enzymatic methods
In glycoconjugates and polysaccharides	Colorimetric assays
Hydrolyzed carbohydrate	HPLC, HPAEC-PAD, GC, GC-MS
Oligosaccharides	HPLC, HPAEC-PAD, GC-MS
Neutral polysaccharides	Separation and extraction techniques, component analysis, methylation analysis, partial acid and enzymatic hydrolysis, mass spectrometry, and ^{13}C and ^{1}H NMR spectroscopy
Proteoglycans	Separation and extraction techniques, component analysis, β-elimination, and enzymatic hydrolysis followed by HPAEC-PAD, and ^{13}C and ^{1}H NMR spectroscopy
Glycoproteins and glycolipids	Cleavage from protein/lipid, lectin binding, component analysis, methylation analysis, enzymatic hydrolysis, mass-spectrometric techniques (fast atom bombardment, laser desorption, and electrospray), ^{13}C and ^{1}H NMR, and two-dimensional NMR.

Fortunately, although the analytical task remains formidable, the full range of monosaccharide ring size and linkage diversity is not found, with most glycans being constructed out of a very limited subset of possible molecular building blocks. However, the analysis of polysaccharides and glycans remains challenging and must be tackled in a systematic manner. There is no single method applicable to this analysis. Even for simple carbohydrates like glucose, a number of methods are used depending on the purpose of the analysis. Complex carbohydrates may consist of several monosaccharide moieties combined in differing ways and proportions and covalently attached to proteins or other molecules. In these cases, it is necessary to determine not only the relative amounts of the carbohydrates present but also their absolute configuration (D or L), their ring size (pyranose or furanose), the anomeric configuration of the linkages (α or β), the linkage positions and sequence, and the nature and location of any inorganic groups or other nonsugar components. Structures are sometimes determined or confirmed by the use of specific lectin binding. Detailed structural analysis of the carbohydrate moieties in glycoconjugates enables the investigation and determination of biosynthetic pathways and biological processes and may offer evidence for the mechanism of metabolic disorders and clinical behavior. As a final refinement, the molecular conformation(s) may have to be determined in order to fully understand the biological relevance of the structure.

1.2 Monosaccharides

There are well-established standardized methods, validated by the International Commission for Uniform Methods of Sugar Analysis (ICUMSA), for analyzing individual low molecular weight carbohydrates in foodstuffs. These make use of nonstoichiometric colorimetric assays for reducing groups or physical methods such

Fig. 1 The commonest monosaccharides present in glycans, with their common abbreviations in brackets. (1) α-D-glucose (Glc); (2) β-D-glucose (Glc); (3) α-D-galactose (Gal); (4) β-D-galactose (Gal); (5) α-D-mannose (Man); (6) β-D-mannose (Man); (7) α-D-glucosamine (GlcN); (8) *N*-acetyl-β-D-glucosamine (GlcNAc); (9) *N*-acetyl-α-D-galactosamine (GalNAc); (10) *N*-acetyl-β-D-galactosamine (GalNAc); (11) α-L-fucose (Fuc); (12) *N*-acetyl-α-D-fucosamine (FucNAc); (13) α-D-glucuronic acid (GlcA); (14) α-D-galacturonic acid (GalA); (15) β-D-glucuronic acid (GlcA); (16) β-D-galacturonic acid (GalA); (17) α-L-arabinose (Ara); (18) β-L-arabinose (Ara); (19) α-D-xylose (Xyl); (20) β-D-xylose (Xyl); (21) α-L-iduronic acid (IdoA); (22) α-L-rhamnose (Rha); (23) 3,6-anhydro-α-D-galactose; (24) 3,6-anhydro-α-L-galactose; (25) β-D-fructose (Fru); (26) *N*-acetyl-β-L-talosaminuronic acid; (27) α-L-galactose; (28) β-D-galactofuranose (Gal*f*); (29) 3-deoxy-β-D-*manno*-oct-2-ulopyrasonic acid (Kdo); (30) β-L-arabinose (Ara); (31) β-D-mannuronic acid (ManA); (32) α-L-guluronic acid (GulA); (33) *N*-acetyl-α-neuraminic acid (NeuAc or sialic acid, SA). Compounds 17, 18, 25, and 28 are furanoses, the rest being pyranoses. Compounds 1–6, 25, and 27–28 are hexoses, 7 an aminohexose, 8–10 *N*-acetamidohexoses, 11, 12, and 22 deoxyhexoses, 13–16, 21, and 31, 32 hexuronic acids, and 17–20 and 30 pentoses. Compounds 2, 4–6, 8, 10–11, 14–15, 17, 20, 22, and 33 are relatively common, whereas compounds 7, 12, 16, 18, 23–24, 26 – 28, and 29–32 are rarely found, the remainder occurring occasionally. Other monosaccharide residues (not shown) are found very rarely, with microorganisms in particular producing a wide variety of rare monosaccharide units. Compounds are also found as derivatives with some or all of sulfate, phosphate, or acetyl groups or as their methyl ethers.

as optical rotation and specific gravity. Enzymatic methods of analysis are becoming more commonly used owing to their specificity and stoichiometry. Monosaccharides derived from more complex carbohydrates by dilute acid hydrolysis may be identified and quantified using gas–liquid chromatography (GC), high-performance liquid chromatography (HPLC), or high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD) by comparison of their elution positions and detector response, respectively, with known standards (Sect. 2.2).

1.3 Oligosaccharides

Oligosaccharides containing between 2 and about 30 sugar residues may be analyzed by means of HPLC or, more commonly, HPAEC-PAD (Sect. 2.2). Known carbohydrate oligomers are usually quantified by comparison with standards. The structures of unknown oligosaccharides may be determined by means of the complementary techniques of mass spectrometry (MS, Sect. 2.3.4) and nuclear magnetic resonance (NMR, Sect. 2.3.5).

1.4 Polysaccharides

Polysaccharides are high molecular weight polymers (>5 kDa) of monosaccharides. They may be linear or branched and may contain just one (homopolysaccharides) or several (heteropolysaccharides) types of monosaccharide. Most polysaccharides have very high molecular weight (≫100 kDa) and possess repeating units of relatively uniform structure. It is this structural unit, together with the molecular weight and/or molecular weight distribution, which is generally sought, rather than an accurate picture of a complete molecule.

The type of polysaccharide may be concluded from the component analysis obtained after acid hydrolysis. The glycosidic linkage positions may be determined by means of methylation analysis (Sect. 2.4.3) or NMR spectroscopy (Sect.2.4.5), and the anomeric configuration of these links may be found by means of their susceptibility to hydrolysis using various specific glycosidases (Sect.2.4.2).

1.5 Proteoglycans

Proteoglycans consist of a number of highly charged polyanionic glycosaminoglycan chains attached to a central protein core via serine or threonine residues. These glycans are distinguished from those occurring in glycoproteins in that they are high molecular weight and essentially unbranched chains of repeating disaccharide units containing carboxyl groups and/or substituted with sulfate ester groups. Analysis of proteoglycans involves the determination of the protein's structure and the positions and local configurations at the linkage regions in addition to the structural determination of the attached glycans.

Glycosaminoglycan chain fragments may be cleaved from the proteoglycans by β-elimination with alkali or enzymic hydrolysis (Sect. 2.4.2) and purified by high-performance anion-exchange chromatography (HPAEC). They may then be analyzed by, for example, ^{13}C-NMR spectroscopy. Although the class of the glycosaminoglycans can be relatively easily deduced on the basis of a component analysis and chemical and enzymatic degradation, the discovery of their

detailed fine structure is much more arduous.

1.6 Glycoproteins

Generally, the most important carbohydrates to cell and molecular biologists are the glycoproteins, where carbohydrate often confers the specificity inherent in many molecular and cellular interactions. These compounds possess diverse structures in which carbohydrate moieties, known as glycans, are covalently attached to proteins. A number of different carbohydrates may be attached in different ways, with specific but varying anomeric configurations, linkage positions, and locations within the sequence. All these parameters must be determined if a complete analysis of the glycoprotein is to be achieved.

Usually the glycans are of relatively low molecular weight, containing between 1 and 20 monosaccharides of between 1 and 5 different types. They often involve complex, highly branched structures (Fig. 2). The same type of monosaccharide may be connected in different ways even within a single glycan group. It is frequently found that several different types of glycan are attached to one protein molecule. Since incomplete glycan biosynthesis or subsequent partial hydrolysis commonly results in glycan heterogeneity, and since such differences in structure often do not significantly influence the chromatographic behavior of the intact glycoprotein, a number of different, but related, glycans may be present and coupled to the same amino acid residue, even in ''purified'' glycoprotein preparations. The analysis of such structures is a serious undertaking for which there are ground rules but no generally applicable, single analytical technique. Methods may vary between laboratories even for similar glycoproteins. There are, however, stages through which any complete analysis must pass.

1. *Isolation and purification.* This involves a number of chromatographic steps such as fast protein liquid chromatography (FPLC), HPLC, gel exclusion chromatography, and lectin affinity chromatography (Sect. 2.5).

2. *Determination of the constituent carbohydrates.* Monosaccharides may be liberated from the glycoproteins by mild acid hydrolysis (e.g. 2 M HCl, 4 h, 100 °C). Once liberated, and after any necessary derivatization, they are separated and determined in one step by either GC or HPLC. This component analysis usually indicates the type of glycans, hence the likely glycan–protein linkages involved.

3. *Cleavage of the intact glycans from the protein moieties.* The different families of glycoprotein glycans require different methods for their cleavage (Fig. 2). As an alternative to the use of enzymes, automated chemical cleavage using hydrazinolysis releases either O-linked or O- and N-linked intact oligosaccharides (Fig. 2). The glycosylation sites may be determined from glycoprotein peptide mapping. The cleaved glycans are often labeled with a radioactive tracer (e.g. by having their reducing ends reduced with sodium borotritide) to make it easier to follow them through their purification.

4. *Glycan isolation and purification.* A combination of size-exclusion HPLC and HPAEC with pulsed amperometric detection (HPAEC-PAD) is commonly used for the purification of glycans. Lectin affinity chromatography is a powerful technique used in their separation.

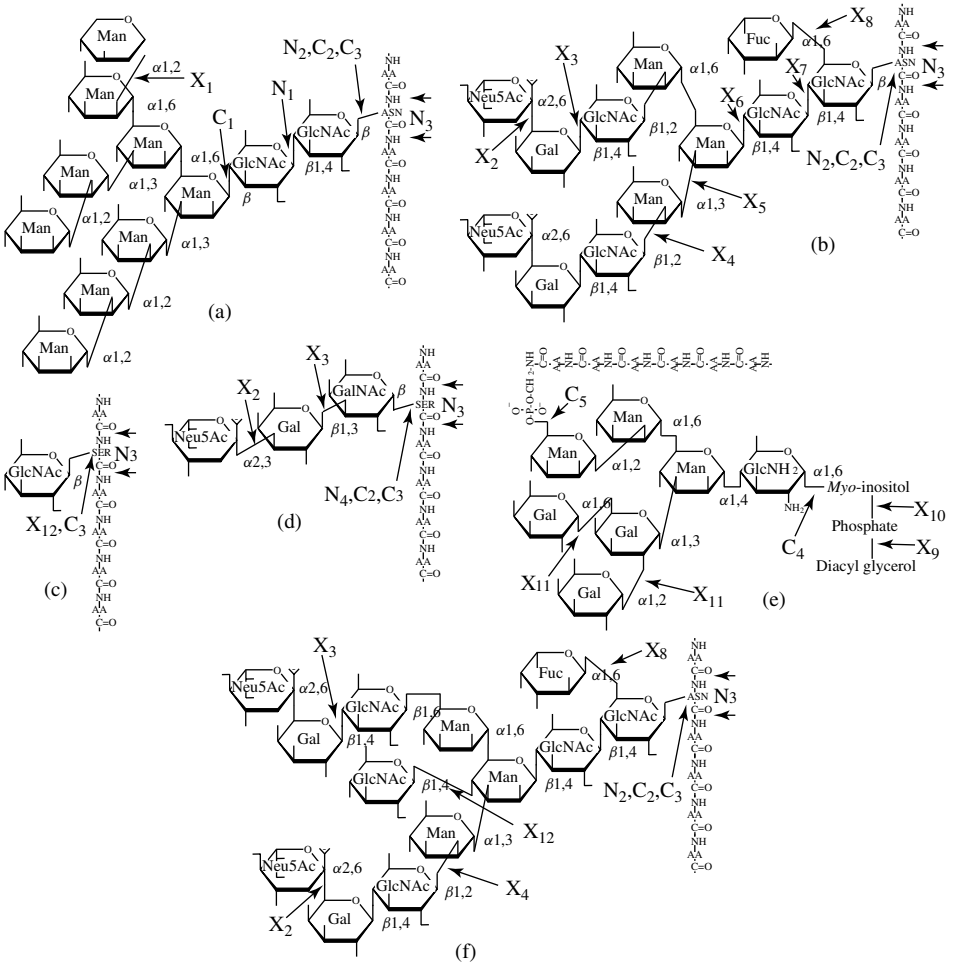

Fig. 2 Examples of the major classes of glycoprotein glycans, showing some methods for their cleavage: (a) *N*-linked high-mannose triantennary, (b) *N*-linked complex biantennary, (c) *O*-linked *N*-acetylglucosamine, (d) *O*-linked complex, (e) glycosylphosphatidylinositol anchor, (f) *N*-linked bisected biantennary. The cleavages may be achieved by the exoglycosidases: X_1, α-mannosidase; X_2, neuraminidase; X_3, β-galactosidase after X_2; X_4, β-*N*-acetylglucosaminidase after X_3; X_5, α-mannosidase after X_4; X_6, β-mannosidase after X_5; X_7, *N*-acetylglucosaminidase after X_6; X_8, α-fucosidase; X_9, phospholipase C; X_{10}, GPI-phospholipase D; X_{11}, α-galactosidase; X_{12}, β-*N*-acetylglucosaminidase; the endoglycosidases: N_1, endoglycosidase H; N_2, peptide *N*-glycosidase F; N_3, pronase; N_4, *O*-glycosidase after X_2; and the chemical methods: C_1, trifluoroacetolysis; C_2, hydrazinolysis; C_3, alkaline sodium borohydride; C_4, nitrous acid; C_5, cold hydrofluoric acid.

5. *Structural studies on the intact glycan.* Much analytical information may be obtained by the use of NMR techniques and mass spectrometry (MS) of the intact glycopeptides. Although it is a powerful tool for determining the presence, sequence, and arrangement of carbohydrates in a glycan chain of up to about 40 residues, mass spectrometry alone is generally not able to distinguish the anomeric type or the linkage positions. NMR, on the other hand, provides a complementary tool that less easily determines sequences but is able to provide detailed information on the anomeric type of the linkages present and the linkage positions. NMR is also often the only experimental technique that can provide the three-dimensional structure. Lectin binding is a powerful, yet simple, technique for discriminating between glycan types.

6. *Complete glycan analysis.* To be sure of any conclusions drawn from spectroscopic studies on an intact glycan, it is necessary to know the complete component composition of all such glycans. In addition, it is usual to confirm the sequence of carbohydrates and their anomeric linkages through the use of specific endo- and exoglycosidases (see Fig. 2 for examples). The linkage positions of the glycan components are still often determined or confirmed by means of methylation analysis.

1.7 Glycolipids

Glycolipids form a diverse group of biological molecules that contain glycans covalently bound to a wide variety of lipid molecules. The intact molecules are generally separated by HPLC. The purified glycolipid molecules may be structurally analyzed by a combination of NMR and MS or by other techniques similar to those applicable to glycoprotein glycans.

2 Key Methods

2.1 The Use of Enzymes in Analysis

Enzymatic methods of analysis, which use the specificity of enzymes to selectively pick out substances from mixtures, are ideally placed for the analysis of complex biological mixtures. There are two ways in which enzymes are generally used:

1. Direct determination of substrates by conversion to products that may be quantified.
2. Structural determination by the ability of enzymes to specifically cleave carbohydrate moieties in di-, oligo-, and polysaccharides and glycoconjugates.

A most important quantitative method is that for glucose. This is not only because glucose is a common carbohydrate analyte but also because it is often hydrolytically produced from other carbohydrates, in their assays. Analysis is by the completely specific conversion of the glucose to 6-phosphogluconolactone with the concomitant conversion of the coenzyme $NADP^+$ to its reduced form NADPH, which absorbs light of 340 nm wavelength. If care is taken to ensure the purity of the enzyme(s), such assays are generally very reliable methods, exhibiting good sensitivity, accuracy, linearity, and precision. All currently accepted assays make use of endpoint determinations; quantification being determined on the basis of a change in color or ultraviolet absorption before and

[a] For abbreviations, see Fig. 1.

after the material has totally reacted. To produce the change in absorption or to pull the reaction in the required direction, several coupled enzymatic reactions are often required.

Enzymes are also used in *biosensors*–analytical devices that convert biological responses directly to electrical signals. A number of such devices are commercially available. The most widespread is the glucose biosensor, which utilizes the reaction of glucose oxidase at the electrode surface. The other major use of enzymes is in the sequence and linkage analysis of polysaccharides and glycoconjugates (Table 2 and Fig. 2).

2.2 Chromatography

Given the wide variety of carbohydrates, it is not surprising that there exists a wide diversity of chromatographic methods for the separation of carbohydrates (Table 3). They generally deliver quantitative data where standards are available. Positive confirmation of the identity of chromatographic peaks (e.g. by MS) may be needed when the analysis involves complex mixtures or if standards are not available. HPLC and HPAEC are the most common methods of chromatographic analysis, with GC still used sometimes for

Tab. 3 HPLC, HPAEC, and GC chromatographic methods for carbohydrate analysis. There are many commercially available columns that will perform similar functions. Choice of appropriate column for a given separation is often due as much to personal experience, cost, and availability of materials as choice of separation chemistry.

Column type HPLC	*Mobile phase*	*Mechanism*	*Analysis*
Quaternary ammonium bonded to PS-DVB, OH^- form	Aqueous	Anion exchange	Monosaccharides, sialic acids, uronic acids, glycans
Anion exchange (aminopropylsilane-bonded silica, OH^- form)	Acetonitrile/water	Hydrophobic and polar	Mono-, di-, and oligosaccharides
Cation exchange (PS-DVB sulfonate, H^+ form)	Acetonitrile/water or aqueous	Ion-moderated partition and ligand exchange	Glycoprotein- and proteoglycan-derived monosaccharides
Cation exchange (PS-DVB sulfonate, Ca^{2+}, Pb^{2+}, Ag^+ forms)	Hot water	Ion-moderated partition, size exclusion, ligand exchange	Alditols, mono-, di-, and oligosaccharides
C_{18}-bonded reversed-phase silica and graphitized carbon	Acetonitrile/water	Hydrophobic interactions	Derivatized carbohydrates and oligosaccharides
Gel-permeation resin or derivatized silica	Aqueous	Size exclusion	Oligosaccharides, glycans, glycoconjugates
Quaternary ammonium pellicular resin	Usually alkaline aqueous	Anion exchange	Mono-, di-, and oligosaccharides and glycans
***Column type GC*[a]**	***Liquid phase***	***Derivatization***	***Analysis***
Dimethyl	Nonpolar	Trimethylsilylated	Mono- and disaccharides
Trifluoropropyl/methyl	Slightly polar	Trifluoroacetylated	Methyl glycosides from glycoproteins
Cyanopropyl/phenyl/methyl	Polar	Peracetylated	Hydrolyzed and reduced methylated glycans

PS-DVB, divinylbenzene/polystyrene resin.
[a]Column type (silicone).

monosaccharides. Capillary electrophoresis (CE) is a powerful, if less used, technique used for separating and classifying glycans and glycoconjugates.

In GC, separation is due to the extractive distillation of the volatile derivatives. The normal protocol uses highly efficient, fused-silica, wall-coated open tubular (WCOT) columns containing a silicone stationary liquid phase. Detection is by means of a flame ionization detector or by mass spectrometry. For low molecular

weight sugars, the choice between HPLC and GC is not often clear-cut, but in general, HPLC has been preferred for the separation and analysis of oligosaccharide mixtures, while GC has been used for more complex mixtures of monosaccharides and disaccharides.

A wide variety of columns has been used for the HPLC of carbohydrates. Sulfonated cross-linked styrene-divinylbenzene columns containing metal-loaded cation exchangers (H^+, Ca^{2+}, Pb^{2+}, or Ag^+) used at moderately high temperatures (~85 °C) or amino-bonded silica columns operating at around ambient temperature are both popular. The cation exchangers act by ion-moderated partition, ligand exchange, and size exclusion, elution being roughly in order of decreasing molecular weight. Amino-bonded silica columns, which use an acetonitrile–water mobile phase, separate by hydrophobic and polar interactions and partition between the acetonitrile-rich mobile phase and the water-enriched stationary phase. Underivatized carbohydrate molecules generally do not absorb light of useful wavelengths, so mass detectors, changes in refractive index (RI), or post-column chromophore-producing reactions are used for detection. Columns are short (generally 5–25 cm) and contain 5 μm, or 3 μm usually spherical particles. Silica-based packing materials have a high rigidity and do not swell in any solvent. Their major weakness is their limited stability in aqueous mobile phases at high pH. Polymeric-based packing materials are more compressible, but they are compatible with all mobile phases including the entire aqueous pH range. Both the inorganic- and the polymeric-based materials offer a wide range of separation modes including reversed-phase, ion-exchange, hydrophilic-interaction, hydrophobic-interaction, and size-exclusion chromatography, which is discussed in Sect. 2.3.2.

UV detectors are not commonly used for carbohydrate analysis, though it is possible to monitor sugars directly at wavelengths below 200 nm. However, at such short wavelengths, low sensitivity and background interference levels often make their use impractical. Refractive index (RI) detectors work on the principle of differential refractometry and have, until recently, been the mainstay of HPLC carbohydrate detection. However, RI detectors have low sensitivity, are temperature-dependent, and cannot be used with a gradient, as they are extremely sensitive to changes in mobile-phase concentration. Pulsed amperometric detectors offer much more versatility and sensitivity and are commonly used in tandem with anion-exchange chromatography.

High-performance liquid chromatography, on strongly basic anion-exchange resins (HPAEC), is generally the method of choice for the analytical separation of disaccharide, oligosaccharide, and glycan mixtures. Coupled with pulsed amperometric detection (PAD), HPAEC-PAD offers high resolution at picomole sensitivity. Polyhydroxyl compounds, such as the carbohydrates, are negatively charged at high pH and are separated by anion exchange with the degree of ionization, composition, size, linkage position, and anomeric configuration all affecting retention. Retention times can be manipulated by altering the strength of the sodium hydroxide eluant or by addition of the more strongly eluting acetate anion (Fig. 3).

Pulsed amperometric detection is a very sensitive technique (~1 ng glucose) that makes use of the electrochemical oxidation, at a gold electrode poised at positive potential, of a tiny proportion of the alkaline anionic carbohydrates. The

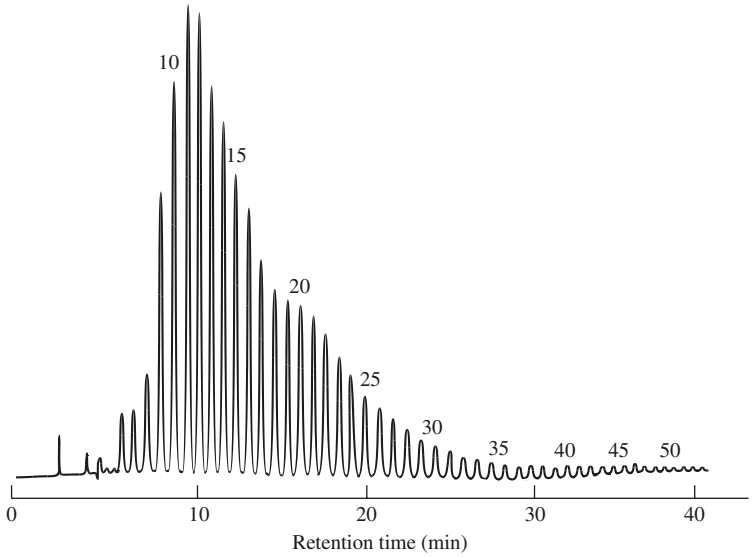

Fig. 3 HPAEC elution profile of the components of debranched wheat amylopectin on a HPIC-AS6 (250 × 4 mm i.d.) column using a gradient of 200 mM sodium acetate at the start, 250 mM at 2 min, 300 mM at 10 min, and 400 mM at 40 min in 150 mM sodium hydroxide solution (1 mL min^{-1}; ambient temperature) and PAD detection. The number on each peak indicates the number of glucose residues. Redrawn from Koizumi et al. (1991) with permission from Elsevier Science.

electrode surface is kept clean by using short pulses of higher positive and negative potentials, thus removing unwanted oxidation products. The advantage of detection with PAD for carbohydrates is that no pre- or post-column derivatization is necessary. Sample preparation is also simplified because only oxidizable analytes will be detected by PAD, and the sensitivity for carbohydrates is orders of magnitude greater than that for the usual contaminant species. HPAEC-PAD has been used, for example, to estimate the chain length of different amylopectins after enzymatic digestion by isoamylase (Fig. 3).

Capillary electrophoresis (CE) is a relatively new technique that provides rapid, highly efficient separations for carbohydrates and possesses several advantages over HPLC owing to its ease of operation, low cost per analysis, and the use of nontoxic chemicals. It provides great resolution by high-voltage (10–20 kV) electrophoresis of mixtures within a polymer-coated fused-silica capillary tube (generally 50 or 70 μm i.d., 375 μm o.d., and between 30 to 100 cm in length). The separation process involves electroendosmotic flow owing to interactions between the charged capillary surface and oppositely charged ions in the buffer. Charged species are separated on the basis of their electrophoretic mobility (charge:mass ratio) and the electroosmotic flow (migration of positive buffer ions to the cathode under the influence of the applied field). Separation can be manipulated by changing either buffer composition or pH. The technique is also applicable to neutral polysaccharides, which can be charged under alkaline

conditions or through complexation with borate or similar ions. Sensitive detection techniques such as pulsed amperometric detection and fluorescence detectors are required owing to the tiny amounts of material separated. Like HPLC, it is suited to the analysis of both polar and nonpolar carbohydrates and it is replacing many of the HPLC techniques. CE offers fast and efficient separation, relatively affordable and durable capillary columns, requires small sample volumes, and has low reagent consumption. It is also a flexible technique available in a number of modes including zone, isoelectric, and micellar electrokinetic. However, it cannot be used for preparative-scale applications.

2.3 Determination of Size and Conformation

Historically, the molecular weight (M) of pure macromolecules, such as glycoproteins, has been determined by ultracentrifugation, using the relationship shown in Eq. (1)

$$\frac{s}{D} = \frac{M(1-\bar{\nu}\rho)}{RT} \tag{1}$$

where both the sedimentation coefficient (s) and the diffusion coefficient (D) are determined under the same conditions. T is the temperature (K), R is the gas constant, $\bar{\nu}$ is the partial specific volume (the effective volume per unit mass) of the solute, and ρ is the solution density. Today, this methodology has been largely replaced by size-exclusion chromatography, field flow fractionation, and laser light scattering methodology.

2.3.1 Light Scattering

It has been known for many years that light is scattered from molecules in solution in a way that depends on the concentration and molecular size of the molecules present. Recently, the use of multiangle laser light scattering (MALLS) has enabled the accurate nondestructive determination of the molecular weight, molecular weight distribution, and radius of gyration of many high molecular weight carbohydrates without the need for known calibrating standards.

Light scattering from molecules in solution may be described by Eq. (2)

$$\frac{Kc}{R_\theta} = \frac{1}{M_w}\left(1 + \frac{16\pi^2}{3\lambda^2}\langle r_g^2\rangle \sin^2(\theta/2)\right) + 2A_2c \tag{2}$$

where

K is an optical parameter given in Eq. (3)

$$K = \frac{4\pi^2 n^2 \left(\frac{dn}{dc}\right)^2}{\lambda^2 N_A} \tag{3}$$

n is the refractive index

$\frac{dn}{dc}$ is the RI increment of the solute.

c is the sample concentration, calculated from the differential RI response

$$RI = K_{RI}c\left(\frac{dn}{dc}\right) \tag{4}$$

where K_{RI} is the instrumental calibration constant,

R_θ is the excess intensity of scattered light at angle theta (θ). M_w is the weight average molar mass (molecular weight, Eq. 5)

$$M_w = \frac{\sum_i n_i M_i^2}{\sum_i n_i M_i} \tag{5}$$

where M_i is the mass of the ith component and n_i is the number of component molecules with that mass.

λ is the wavelength of the scattered light in vacuum.

A_2 is the second virial coefficient, a measure of the solute–solvent interaction that may be important for charged molecules at low ionic strength or where the solution is moderately concentrated.

N_A is Avogadro's number

$\langle r_g^2 \rangle$ is the z-average mean square of the radius of gyration (R_G, which reflects the average displacement of each residue from the molecular centre. Eq. 6)

$$R_G^2 = < r_g^2 > = \frac{\sum_i n_i M_i^2 \langle r_g^2 \rangle_i}{\sum_i n_i M_i^2} \qquad (6)$$

Use of Eq. (2) normally involves extrapolation of theta to zero angle. The molecular weight and radius of gyration are determined by plotting $\frac{Kc}{R_\theta}$ against $\sin^2(\theta/2)$ (Zimm plot) to yield an often almost linear curve whose intercept gives M_w and whose slope at low angles gives the radius of gyration and hence the hydrodynamic volume.

When combined with the separating power of high-performance size-exclusion chromatography (HPSEC), light scattering forms an important tool for the polysaccharide analyst. A typical SEC-MALLS system includes an RI detector, placed after the MALLS detector, for determining the concentration of the eluting polysaccharides.

2.3.2 Size-exclusion Chromatography

Size-exclusion chromatography (SEC) has proved to be a useful technique for separating carbohydrates on the basis of their molecular size. Molecules are eluted in order of decreasing molecular size from a stationary phase containing a wide range of different size pores, allowing greater access and hence slower elution for smaller molecules. SEC has difficulty in determining the absolute molecular size of polysaccharides in which there is a requirement for similar carbohydrates, of known molecular weight, for calibration. In combination with MALLS detection, however, exact values for polysaccharide molecular weight polydispersity can be routinely determined.

The drawback of this technique is that separation of very large molecules is relatively poor due to the difficulty in manufacturing the required high-performance, high-porosity resins. Also, there can sometimes be losses or poor chromatography due to nonspecific absorption. For these reasons, SEC is to some extent being replaced by field flow fractionation.

2.3.3 Field Flow Fractionation

Field flow fractionation (FFF) is a technique for separating polymers on the basis of their size. In combination with MALLS, it is capable of determining molecular weight distributions of complex polysaccharides and delivering far superior resolution to that obtained by SEC-MALLS for high molecular weight materials (>100 000 Da). The separatory principle of the method is the reduction in the diffusion coefficient with increase in molecular size (more exactly, their hydrodynamic size). Molecules to be separated are carried through a thin rectangular channel with at least one of the broader surfaces permeable to small molecules and aqueous solvent (Fig. 4). An introduced cross flow forces the molecules against this permeable surface. Larger molecules with low diffusion constants are left in the slow-moving carrier stream at this surface, whereas molecules with greater diffusion coefficients are able to leave the surface and be carried along more quickly by the fast stream of aqueous solvent further out. Thus, molecules will leave the system in order of their diffusion

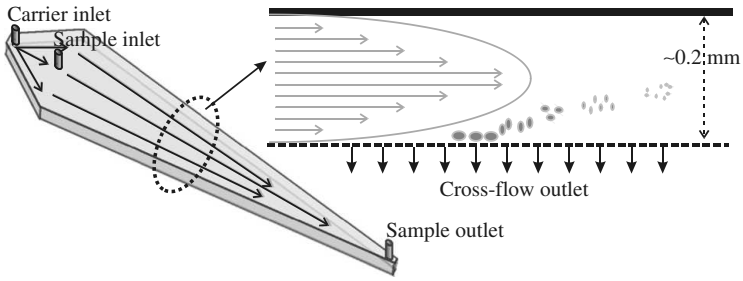

Fig. 4 Outline of asymmetric flow field flow chromatography. Sample (about 100 µL containing 100 µg) is injected and concentrated onto the crossflow membrane. Eluant then carries it along the surface of the crossflow membrane to the sample outlet. Eluant but not sample leaves through the crossflow outlet at a rate determined by the flow rate and the chamber's asymmetry, thus maintaining the sample close to this surface. Molecules possessing greater diffusivity are able to enter the faster flowing stream above the surface and are carried out of the chamber first.

coefficients with those that have higher values (i.e. smaller molecules) exiting first and the largest molecules exiting last. The concentrations of the chromatographed material on exit are usually determined from the RI changes and their absolute molecular weights are determined using MALLS. As the separation only depends on the diffusion coefficient and there is effectively no absorption, this method is capable of giving the absolute hydrodynamic size of molecules plus useful information concerning the molecules' conformations and structures (e.g. the degree of chain branching).

2.3.4 Mass Spectrometry (MS)

Mass spectrometry (MS) is a sensitive and powerful technique for the analysis of glycans. It involves the production of ionized carbohydrate moieties that are in the gas phase. The charged ions move in a magnetic field along curved paths, which are determined by the imposed magnetic field and by the ratio of their mass to their charge (m/z). Usually, singly charged cations are produced most abundantly and may be detected with masses up to several kilodaltons with an accuracy approaching 1 ppm. The key stage of the technique is the ionization step. Sugars are not normally volatile and must be derivatized or otherwise persuaded to enter the gas phase.

In electrospray ionization mass spectrometry (ES-MS), a strong electric field is applied between the end of a capillary tube containing the sample solution and a counter electrode, to disperse the emerging sample into an aerosol of highly charged droplets. As the droplets evaporate, assisted by the flow of warm gas, multiply charged ions emerge free from solvent (Fig. 5). This rapid and sensitive method produces intact molecular ions of even very large molecules and allows the determination of the molecular weight of glycoproteins with an accuracy of 0.01% using as little as 1 pmol of sample. Thus, glycosylation heterogeneity can be accurately quantified. As an example, the ES-MS of the carboxy-terminal half of hen ovotransferrin gives 3 major peaks centered on molecular masses of 40 220, 40 056, and 39 854. This indicates microheterogeneity

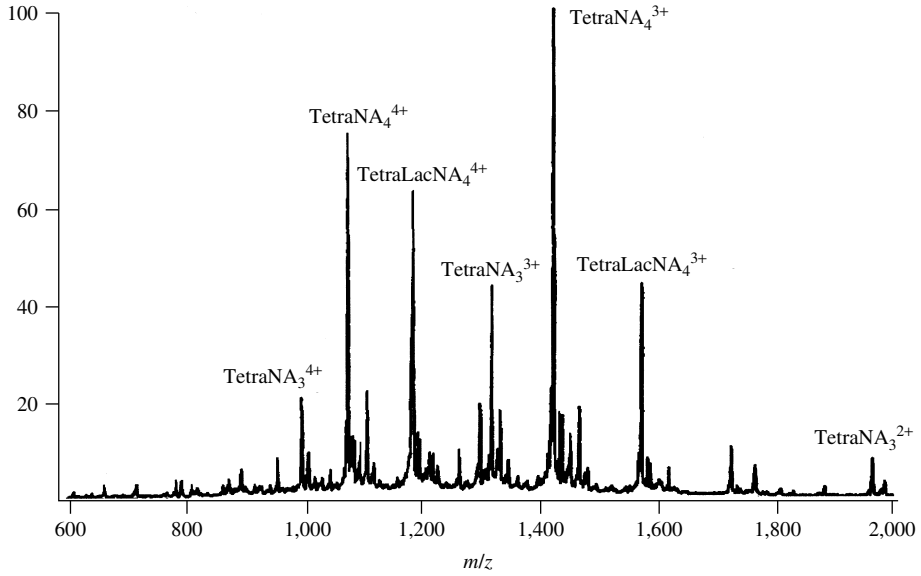

Fig. 5 ES-MS of oxidized, reduced ($NaBD_4$), and methylated glycan from recombinant erythropoietin. ES-MS produces multiply charged ions. This example is centered on triply positively charged ions. Periodate oxidation, which oxidizes *cis*-diols only, of the glycans was used to resolve isomeric structures and discover linkage positions. For example, the most abundant peak ($TetraNA_4$, m/z 1422.4, mass 4267.2 Da) is derived from a tetraantennary glycan containing four terminal neuraminic acid residues and a fucosyl residue (4633.5 Da). The other major species, Tetra NA_3 and $TetraLacNA_4$, are derived from similar glycans but with an *N*-acetylneuraminic acid residue loss and an *N*-acetyllactosamine residue gain respectively. Redrawn from Linsley et al. (1994) with permission from Elsevier Science.

due to the absence of first a hexose and then an *N*-acetylhexosamine residue. ES-MS is ideally suited for direct interfacing to HPLC and capillary electrophoresis. It is far less able to handle buffers and detergents than MALDI-MS, however.

Matrix-assisted laser-desorption ionization mass spectrometry (MALDI-MS) gives results similar to those obtained from ES-MS but can extend the range of detectable molecular ions. In this method, the ionization of dry samples is achieved through the use of a short pulse of intense UV-laser light in the presence of a 100-fold excess of a UV-absorbing organic molecule (known as the matrix, e.g. 2,5-dihydroxybenzoic acid). Even very large molecules can be vaporized and ionized as MALDI is capable of determining molecular weights, in exceptional cases, of up to m/z 300 kDa using time-of-flight (TOF) detection. It requires only femtomoles to picomoles of material, no sample derivation, and tolerates more buffer and detergent than other MS methods. Although able to handle proteins, it has not had similar success, so far, with natural polysaccharides in the upper part of this range (>25 kDa) and seems to work best with oligosaccharides below 5 kDa. This may be partly due to the polydispersity of such samples and partly due to the inherently poor resolution of MALDI-TOF MS.

Mass spectrometry must generally be combined with other analytical methods of analysis as it cannot distinguish between

isomeric sugar residues and cannot easily provide the linkage and stereochemical information of NMR.

2.3.5 NMR Spectrometry

The nuclei of many atoms (e.g. ^{1}H, ^{13}C, ^{15}N, ^{31}P) act as spinning magnets that can orient themselves with or against an external magnetic field. The strength of this imposed magnetic field determines both the frequency at which the nuclei rotate (at high field strengths, the ^{1}H resonance frequencies are 400–600 MHz) and the resolution of the NMR spectra. The very small difference in energy between the orientations of the spin of a nucleus is affected by local variations in the magnetic field due to neighboring nuclei and can be used to differentiate between the nuclei and to provide information on neighboring nuclei and their relative orientation. The differences in the magnetic environment of the nuclei are reported in terms of the relative shift, in parts per million, of the applied magnetic field due to the local molecular magnetic field relative to a known structure. For protons, shifts are usually reported downfield (i.e. higher ppm) from the methyl protons of sodium 3-trimethylsilyl-1-propanesulfonate.

^{1}H-NMR spectroscopy is an extremely powerful and elegant technique for the determination of the structure of glycans, although it is between three and six orders of magnitude less sensitive than mass spectrometry. It can provide information about the number and variety of the component carbohydrate residues, on how they are joined together, and can indicate the presence or absence of noncarbohydrate groups. Taken together with component and methylation analysis, ^{1}H-NMR spectra often allow the unambiguous assignment of the complete molecular structures of purified glycans and the composition of less-purified mixtures of glycans.

The key features of carbohydrate NMR are the downfield shifts owing to the spatial proximity of oxygen atoms. Proton NMR carbohydrate spectra contain a mainly unresolved heap of signals between 3.5 and 4 ppm with relatively few resolved outlying peaks (Fig. 6, top). These outliers are termed *structural reporter groups* and contain generally well-resolved anomeric signals (H-1) with greater shifts (4.4–5.4 ppm). As the anomeric carbon (C-1) is bonded to two oxygen atoms, these anomeric ^{13}C and ^{1}H atoms are easily distinguishable, providing important inroads into the structural determination. Their chemical shifts and coupling constants indicate the sugar residues involved, together with the types and anomeric character (i.e. α or β) of the glycosidic linkages and their ring size (pyranose or furanose).

Other reporter groups also provide useful well-resolved resonances. The methyl protons and carbon (^{13}C) atoms in deoxysugars are upfield (i.e. at lower ppm) and the carboxylate carbon (^{13}C) atoms in uronic acids are downfield. Thus, the position of fucose residues may be confirmed by the shifts of their H-5 (4.0–4.8 ppm) and methyl hydrogen (~1.2 ppm) atoms. Signals due to mannose H-2 atoms (4.1–4.2 ppm) help confirm the type of antennary structure indicated by the anomeric proton shifts. The shifts of both the axial (~1.7 ppm) and equatorial (~2.7 ppm) H-3 atoms in sialic acids are characteristic for the type and configuration of their glycosidic links and may be indicative of their position in the chain. The shifts of the hydrogen atoms in acetyl groups (2.0–2.1 ppm) are very useful in indicating the structure local to *N*-acetylhexosamine and sialic acid residues.

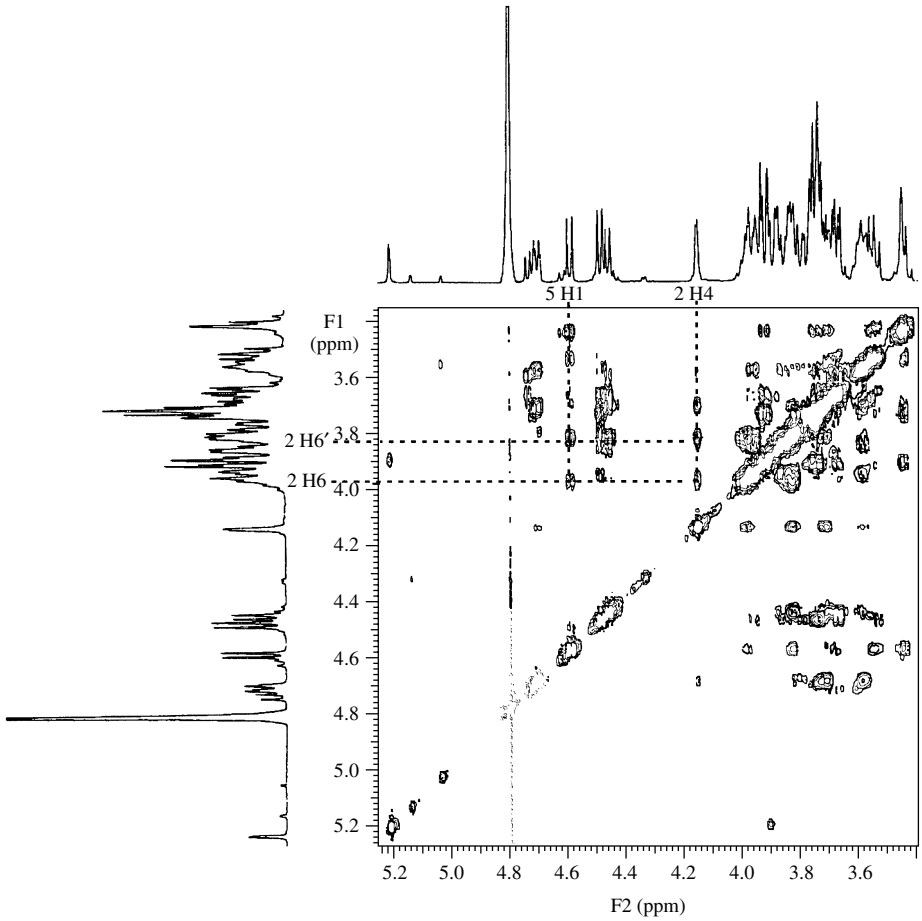

Fig. 6 Two-dimensional ROESY spectrum of a pentasaccharide derived by the action of a rat serum β-(1 $\rightarrow$ 6)-D-*N*-acetylglucosaminyltransferase. A ROESY spectrum gives through-space information concerning the closeness of protons. The diagonal consists of the 1D spectrum also shown to the top and side. The off-diagonal peaks show close atoms (<0.5 nm). The anomeric proton on the newly inserted residue (5H1, GlcNAc) is shown to lie close to the two protons on the 6-position of the second residue (2 H6 and 2 H6′, Gal) that in turn lies close to the 4-proton on this Gal residue (2 H4). Thus, the linkage of this GlcNAc residue to the 6-position on the second galactose residue was confirmed. Redrawn from Maaheimo et al. (1997) with permission from Elsevier Science.

^{13}C-NMR requires substantially larger samples than ^{1}H-NMR both because of the intrinsically lower sensitivity (1.6%) of ^{13}C nuclei relative to ^{1}H and because of the low natural abundance of ^{13}C relative to ^{12}C (1.1%). Advantage is taken of this lower abundance as it also simplifies the spectra inasmuch as ^{13}C–^{13}C coupling is virtually nonexistent. It has also proved popular for the determination of naturally acetyl-derivatized sugar residues.

Polysaccharides, glycoproteins, and large glycans are usually run in D_2O ($^{2}H_2O$). Working in D_2O eliminates the

less-well-defined exchangeable hydroxyl protons and the vast excess (110 M) of H_2O protons. Intramolecular hydrogen bonding may be investigated by dissolving the carbohydrate in per-deuterated dimethyl sulfoxide (DMSO) when the hydroxyl (and amine) protons do not exchange with solvent and give useful information. In some cases, hydrogen bonding may be determined from proton exchange in mixed H_2O, HOD, and D_2O solvents where solvent exposure may be quantified from the differential shifts in proton and carbon spectra.

Although 1D proton NMR spectra can be used as fingerprints to enable structural determination where databased structures exist, they are generally too complex to assign fully even for relatively simple oligosaccharides. ^{13}C spectra are simpler but are also usually too complex to use without the availability of fully assigned NMR spectra from suitable known structures for guidance. The structures of unknown carbohydrates generally demand a variety of through-bond (COSY), through-space (NOESY), and heteronuclear ^{13}C–^{1}H 2D NMR techniques using high-field spectrometers (600 MHz) for their elucidation.

Complete assignment of ^{1}H NMR and ^{13}C NMR resonances usually starts with the well-resolved anomeric H-1 or C-1 peak using 1D NMR. The proton resonances can then be assigned sequentially using through-bond techniques. The anomeric conformation may be confirmed from the size of the anomeric $^{1}J_{C-H}$ coupling constant, which is typically 170 Hz for axial hydrogen and 160 Hz if equatorial. Structural conformations may be given by the $^{3}J_{H-H}$ coupling constants, which obey a Karplus relationship (Eq. 7).

$$^{3}J = A\cos^{2}(\theta) - B\cos(\theta) + C \qquad (7)$$

where A, B and C are fitted parameters derived from a number of known trainer molecules. The cosine nature of Karplus curves means that it gives one to four possible angles every 360° for a given ^{3}J (Fig. 7). Simple molecular modeling can usually make a choice between these, as often only one conformation is structurally reasonable. For example, the

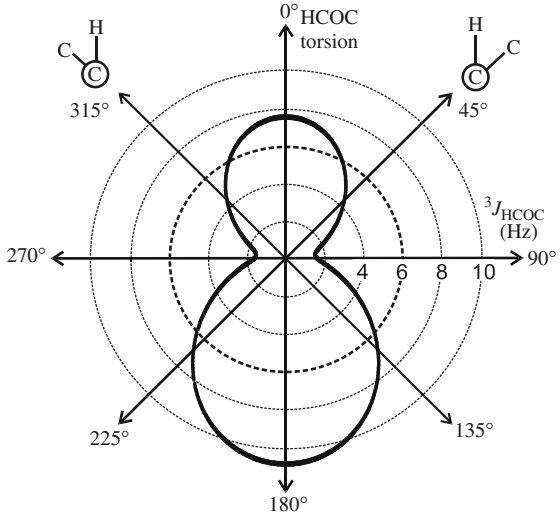

Fig. 7 The Karplus relationship $^{3}J = A\cos^{2}(\theta) - B\cos(\theta) + C$. The coupling constants involving the glycosidic linking torsions ($^{3}J_{COCH}$) A, B, and C are 7.6, 1.7 and 1.6 Hz respectively. It can be noted that for any experimental value of ^{3}J, there may be up to four possible torsional angles (e.g. a $^{3}J_{COCH}$ of 6 Hz may be derived from a torsion of 28°, 131°, 229°, or 332°).

anomeric configuration of glucopyranose and galactopyranose are easily observed, from the $^{3}J_{H1-H2}$ coupling constant, as the H-1 and H-2 protons of the beta anomers are trans-diaxial (~180°) giving large couplings, whereas those in alpha anomers are gauche (~60°) with small couplings.

2.3.6 Molecular Modeling

Molecular modeling techniques treat structures as mechanical entities in which bond lengths, angles, and torsions are treated as springs requiring forces to move them from their preferred values. Together with a consideration of atomic charges and van der Waals interactions, the structure of the molecule is optimized, giving preferred conformations. Various molecular dynamics and random walk molecular mechanics (RAMM) methods exist to ensure that the molecule does not settle into biologically irrelevant local potential energy minima.

The additional information available from such molecular modeling is particularly useful for carbohydrates, when compared to proteins, as carbohydrates generally do not form crystal structures (if they form them at all) with similar conformations to their conformation in freely dissolved solution. The information is also useful for clarifying NMR structural analyses where the coupling constants may not be measurable and where there are mixed conformational populations present.

2.4 Linkage Analysis

2.4.1 Glycan Detection

There are several methods available for detecting the presence of glycans attached to proteins (glycoproteins) and lipids (glycolipids). One way is to oxidize all the pairs of adjacent hydroxyl groups (i.e. *cis*-diols) in the carbohydrate to aldehyde groups, using periodate, followed by covalent coupling to hydrazide derivatives of biotin or the steroid digoxigenin. The respective labeled glycoconjugates may be detected by an enzyme immunoassay using streptavidin or a digoxigenin-specific antibody conjugated to alkaline phosphatase. This procedure may be applied *in situ* for the detection of nanogram quantities of glycoproteins, previously separated by sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS-PAGE) and blotted onto nitrocellulose membranes. More specific oxidation methods, such as the use of galactose oxidase or prior specific enzyme hydrolysis (Sect. 2.4.2), may allow the detection of glycan subclasses.

2.4.2 Glycan Release and the Use of Enzymes

The carbohydrate structures in glycoproteins are normally investigated after they are released from the protein and chromatographically separated from each other. There are a number of methods by which these glycans may be released; some utilize specific enzymes (Table 2), whilst others use chemical methods (Fig. 2).

2.4.3 Methylation Analysis

Methylation analysis is a powerful and widely used method for the determination of the glycosidic linkage positions in the structural analysis of glycoprotein, as well as glycolipids, glycans, and polysaccharides. It involves replacing all the free hydroxyl groups with methyl ether groups (Fig. 8). The methylated polysaccharide is then hydrolyzed, converted to alditols, acetylated, and analyzed by GC or GC-MS.

The carbohydrate is initially dissolved in dry DMSO. In the presence of a very strong base, such as sodium hydride or potassium *tert*-butoxide, and the absence

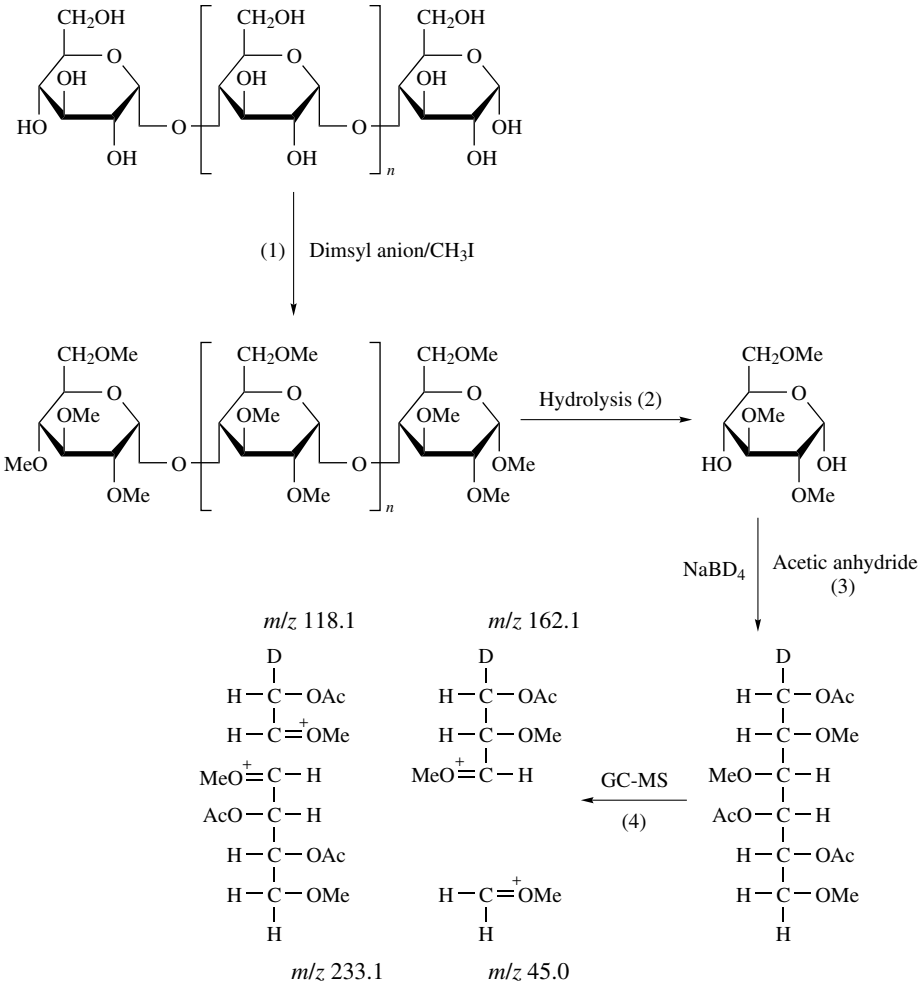

Fig. 8 Methylation analysis. In this technique all the free hydroxyl groups in the intact glycan are methylated (1). The fully methylated glycan is then hydrolyzed (2), reduced, and acetylated (3). The linkage positions may be deduced from the positions of the methyl and acetyl groups in the resultant partially methylated alditol acetates, as determined using GC-MS. The ring hydrogen atoms are omitted for the sake of clarity. The breakdown of such compounds in EI-MS occurs primarily between neighboring methyl ethers. Secondary fragmentation then occurs by the elimination of the neutral molecules acetic acid (CH_3COOH, −60 Da), methanol (CH_3OH, −32 Da), ketene (CH_2CO, −42 Da), and formaldehyde (CH_2O, −30 Da) from these primary fragments. Thus, the *m/z* 162 fragment gives rise to an *m/z* 102 peak. The deuterium atoms in these structures distinguish the C-1 atoms from the C-6 atoms.

of water, the DMSO is converted into the dimsyl anion, which is then able to convert all the free hydroxyl, carboxyl, and amino groups to their anions. Methylation of the polyanion is then carried out using methyl iodide. At the end of the reaction, the methylated product is hydrolyzed with acid to its component partially methylated

residues. These have free hydroxyl groups in the positions where they were linked to each other and methyl ether groups where the original carbohydrate had free hydroxyl groups. The products are further derivatized to render them volatile and are analyzed qualitatively and quantitatively by GC coupled to electron impact ionization spectroscopy (EI-MS). This MS produces very energetic ions that fragment readily, nearly always resulting in the loss of an intact molecular ion. It is the breakdown pattern rather than the molecular ion that enables us to distinguish between the methylated carbohydrate residues (Fig. 8). The positions of the acetyl groups indicate where the unmethylated free hydroxyl groups were in the partially methylated hydrolyzed sugars, thus showing where the residue was substituted. However, it gives no information on either the sequence of these residues or their anomeric conformation.

Naturally methylated or acetylated glycans may be analyzed by methylation, as just described, but using deuterated methyl iodide or acetic anhydride to distinguish between the natural and chemically derivatized sites by their different masses.

2.4.4 Mass Spectrometry

Mass spectrometry is capable of providing sequence information in addition to its previously described use, determining molecular weight. In FAB-MS, as little as 1 pmol of glycan sample is bombarded with an accelerated beam of neutral atoms (e.g. Xe, Cs) in a vacuum. This causes desorption of the sample from the liquid surface, forming a characteristic molecular ion plus a wealth of structurally diagnostic fragment ions derived from it. The structure of a sample is determined given the known fragmentation patterns of related model structures. Improved spectra can usually be obtained by the use of fully methylated or acetylated carbohydrates. As fragmentation predominantly occurs between glycosidic links, the breakdown pattern may give an abundance of information concerning the glycan's sequence. As an example, the biantennary glycan (Fig. 2b) when fully methylated gives the following m/z peaks:

2492	$(\text{Neu5Ac} \rightarrow \text{Gal} \rightarrow \text{GlcNAc} \rightarrow \text{Man})_2\text{Man} \rightarrow \text{GlcNAc})^+$
1029	$(\text{Neu5Ac} \rightarrow \text{Gal} \rightarrow \text{GlcNAc} \rightarrow \text{Man})^+$
825	$(\text{Neu5Ac} \rightarrow \text{Gal} \rightarrow \text{GlcNAc})^+$
376	$(\text{Neu5Ac})^+$

Although linkage information is produced, the MS is not able, in this case, to differentiate the order of the hexoses or *N*-acetylhexosamines, nor is it able to determine the linkage positions.

Tandem mass spectrometry (MS/MS) utilizes two or more mass-selection devices in series so that the known ion from one analyzer may be selected and induced to give daughter fragments that are determined using a second analyzer. It can provide complete sequence, branching, and linkage information. Even pyranose and furanose ring systems may be distinguished owing to differences in their cleavage patterns. Tandem mass spectrometry can be used with FAB, ESI, or MALDI and the use of post source decay (PSD) in MALDI-TOF or collision-induced dissociation (CID) in ESI has proved particularly useful as the extent and distribution pattern of fragments is highly reproducible.

2.4.5 NMR Spectroscopy

The power of NMR is most useful when it is used to determine the sequence, linkage positions, and conformation of carbohydrates. Linkage and sequence

information is commonly obtained using the off-diagonal peaks apparent in two-dimensional NMR (Fig. 6). Spectra can be obtained in a number of ways, by such techniques as COSY and NOESY after a full assignment of the ^{1}H and ^{13}C spectra. In particular, COSY techniques indicate neighboring connected nuclei, whereas NOESY techniques give indication as to the closeness of groups through space, the effects of both being due to perturbations caused to each other's atom's local magnetic field. Linkages can be determined from the $^{3}J_{CH}$ scalar coupling through and across glycosidic bonds and from interglycosidic ^{1}H NOE effects using NOESY, which gives those protons that are in close proximity (less than about 0.5 nm).

By spreading out the NMR spectra over two or more dimensions, all the spectral peaks may be unambiguously assigned to atoms in the glycan, fully confirming its structure. Such spectra also allow the determination of the positions of noncarbohydrate substituents such as sulfate and phosphate groups.

Sequences may be determined from through-space connectivities. However, with increasing size above about 20 glycosyl residues, it becomes increasingly difficult to delineate branch locations unambiguously. NOE effects are also difficult to interpret in the presence of significant internal molecular motion, owing to positional averaging. Although NMR is difficult to apply to many polysaccharides, the presence of repeating units can be identified from the NMR spectra of oligomers and then quantified in the polymers.

Linkage positions may also be discovered by determination of the position of the free hydroxyl groups, giving information similar to that obtained from methylation analysis (Sect. 2.4.3), but nondestructively. ^{1}H NMR spectra in H_2O (~10% D_2O) and D_2O are compared to identify the position(s) of the hydroxyl groups.

The biological roles of oligosaccharides and polysaccharides are related to their conformations. This mainly depends on the trans-glycosidic torsional angles connecting the carbohydrate units (Fig. 9).

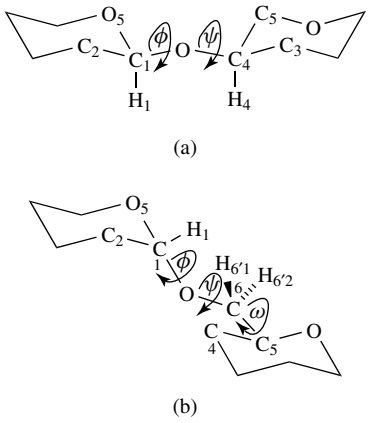

Fig. 9 The torsions and possible coupling constants involved in the anomeric linkages in oligosaccharides and polysaccharides. (a) Torsions ϕ (phi) and ψ (psi) are defined as the clockwise torsions $O_rC_aO_aC_n$, and $C_aO_aC_nC_{n-1}$ respectively, where *r*, *a*, and *n* represent ring, anomeric, and structural number, respectively. The relevant and useful coupling constants are $^{3}J_{C_1OC_4C_3}$ giving ψ and $^{3}J_{C_2C_1OC_4}$ giving ϕ and $^{3}J_{C_1OC_4H_4}$ and $^{3}J_{H_1C_1OC_4}$. (b) Linkages to the terminal carbon atom may involve an exocyclic link; the additional linking torsion ω (omega) is defined as the clockwise torsion $O_aC_nC_{n-1}C_{n-2}$. The relevant coupling constants are $^{3}J_{C_1OC_6C_5}$ giving ψ and $^{3}J_{H_1C_1OC_6}$, $^{3}J_{C_1OC_6H_{6'1}}$, $^{3}J_{C_1OC_6H_{6'2}}$, $^{3}J_{C_2C_1OC_6}$, $^{3}J_{H_{6'1}C_6C_5C_4}$, and $^{3}J_{H_{6'2}C_6C_5C_4}$.

Conformational analysis requires independent data for each independent torsion angle (ϕ, ψ, and sometimes ω) and, where mixtures of conformations exist, the relative population occupancy of each. These may be available from interresidue proton NOE (e.g. between the anomeric proton and the proton on the linkage carbon, $H-C_1-O-C_n-H$) and the $^3J_{COCH}$, $^3J_{COCC}$, $^3J_{CCCH}$, and $^2J_{COC}$ coupling constants, but the cosine nature of the Karplus equation for ^3J coupling means modeling may be required. Whilst the conformation of rigid oligosaccharides can be directly derived from NOESY data, the upper and lower bounds of the possible distances from NOESY often enclose a large number of ϕ and ψ combinations. As multiple conformations are often in fast equilibrium on the NMR timescale and NMR data is effectively time-averaged, unrealistic putative torsional angles may arise and must be discriminated using molecular modeling (Sect. 2.3.6).

Although NMR is an extremely powerful tool, it has not yet been proved possible to use it on intact glycoproteins because of the complexity of the multitude of overlapping peaks in the spectra. A further limitation of NMR is that it requires samples of at least about 25 nmol (i.e. milligram amounts).

2.5 Use of Lectins

Lectins are widespread and serve in many biologically significant activities, such as agglutinating cells and precipitating glycoproteins and polysaccharides. Because of this, many lectins are extremely toxic. The carbohydrate binding sites are large and able to distinguish complex carbohydrate structures (Table 4).

For this reason, lectins are used in blood banks to identify blood groups. In some cases, lectin binding is able to discriminate between structures that are otherwise difficult to distinguish; examples include α-2-6- and α-2-3-linked terminal sialic acids.

Lectins may be immobilized on Sepharose columns and used to separate, purify, and type glycoconjugates by a process of affinity chromatography. Submicrogram amounts of glycoconjugates may be differentiated by means of their specific binding to lectins that have been covalently labeled with biotin or digoxigenin. A range of lectins may be used; those bound are detected by enzyme immunoassay using streptavidin or a digoxigenin-specific antibody, respectively, conjugated to alkaline phosphatase in a similar manner to that described in Sect. 2.4.1.

Keywords

Monosaccharide
The most basic carbohydrate molecule that cannot be divided into simpler sugars by hydrolysis.

Oligosaccharide
A linear or branched chain composed of a small number of monosaccharides (2 to 10 or 20) that can be broken down into simpler sugars via hydrolysis.

Polysaccharide
A polymer composed of a large number of monosaccharides, at least more than 10 to 20, and usually many hundreds or thousands of monosaccharide units arranged in repeated structures.

Glycoconjugate
A molecule in which an oligosaccharide is covalently linked to a protein or a lipid, forming either a glycoprotein or a glycolipid, respectively.

Glycan
Equivalent to polysaccharide but usually refers to the sugar chains of glycoconjugates.

Glycosaminoglycan
A heteropolysaccharide chain usually composed of a hexosamine and glucuronic acid as seen in proteoglycan.

Glycoprotein
A molecule in which an oligosaccharide is covalently linked to a protein.

Proteoglycan
A subclass of glycoproteins with large heteroglycan chains usually composed of a hexosamine and glucuronic acid.

Glycolipid
A molecule in which an oligosaccharide is covalently linked to a lipid.

Glycosphingolipid
A subclass of glycolipid in which an oligosaccharide is covalently linked to the lipid sphinganine.

Lectin
A carbohydrate binding protein or glycoprotein of nonimmune origin that binds noncovalently to carbohydrates with specificity and selectivity.

Carbohydrate antigens are polysaccharides and glycocojugates of multiple structural configurations that are able to evoke carbohydrate-specific antibodies and react with these antibodies. Although recognition of carbohydrates as antigens began with the study of microbial polysaccharides, the scope of investigation of carbohydrate antigens has since been substantially extended. Carbohydrates are unsurpassed in generating structural diversity and are prominent in surface display. They contain valuable biological information and are characteristically recognizable by either soluble or membrane-bound cellular proteins. In the higher eukaryotic species, expression of cellular glycoconjugates, and especially their complex carbohydrate structures, is frequently cell type–specific or tissue-specific. In microbes, many sugar chains, including those displayed on the surface of a microbial cell and those secreted outside it, have been recognized as ''signatures'' of specific pathogens. Exploring the biological information content of sugar chains is the current focus of postgenomic research. Carbohydrate antigen, as a classical immunological topic, has gained renewed interest in the new millennium.

1 Classifications

Carbohydrate antigens exist in multiple structural configurations, including polysaccharides, glycoproteins, glycolipids, glycosphingolipids, glycosaminoglycans, and proteoglycans. Given their origins, carbohydrate antigens were traditionally classified as microbial antigens and alloantigens. Microbes produce the former; the latter are expressed by mammalian cells. Carbohydrates may be ''complete-antigens,'' such as microbial polysaccharides, in that they are able to induce reactive antibodies in certain species. They may also be components or antigenic determinants of glycoconjugates. Such carbohydrate moieties, or oligosaccharides, are termed *haptens* in immunology. They determine the specificity of an immune response but are not being able to evoke an immune response in their free, unconjugated forms. Consideration of glycoconjugates as carbohydrate antigens makes it necessary to further classify carbohydrate antigens into two large immunological categories, the T-dependent (TD) and T-independent (TI) forms of carbohydrate antigens.

Therefore, different methods have been used to classify carbohydrate antigens. Their relationship is summarized in Table 1. We must emphasize that this table is an attempt to illustrate how researchers of different scientific disciplines ''see'' a

Tab. 1 Classification of carbohydrate antigens.

	TI-1	*TI-2*	*TD*
Microbial antigens			
Polysaccharide	No	Yes	No
Lipopolysaccharide	Yes	No	No
Glycoprotein	No	No	Yes
Glycolipid	No	Yes	No
Allo- & xenoantigens			
Glycoproteins	No	No	Yes
Glycolipids	No	Yes	No
Glycosaminoglycans	No	Yes	No
Proteoglycans	No	Yes	Yes (?)

Notes: TI: T-independent; TD: T-dependent.

common object and work together to better understand the object – carbohydrates. When a specific molecule is involved, experiments must be conducted to learn its immunological properties. Diversity of carbohydrate antigens and the complexity of host immune systems have made it difficult to summarize a general scheme for the antibody responses induced by carbohydrate antigens. Seeing exceptions regarding the TD and TI characteristics of an antigen from a given class may not be surprising.

1.1 Microbial Antigens

Microbial carbohydrate antigens include polysaccharides, glycolipids, and glycoproteins. Polysaccharides may be cell wall components of microorganisms, such as lipopolysaccharides (LPS) in gram-negative bacteria, or capsules in gram-positive bacteria, known as *capsular polysaccharides*. They may also be secreted as exopolysaccharides, forming slime-like amorphous materials to trap microbial cells in a viscous matrix. These polysaccharides are all located on the cell surface and are, therefore, of importance in the recognition and immune response of a higher organism to microbial infections. Glycoproteins were recently recognized in a number of bacterial species. By contrast, they were found essentially in almost all membrane-bound or secretory proteins of viruses and many parasites.

1.2 Alloantigens and Xenoantigens

Eukaryotic cells also express carbohydrate antigens, notably alloantigens of the human blood group systems and xenoantigens expressing α-Gal epitopes. The former is an allogenic marker of human red blood cells and is responsible for the rejection of an allogenic blood transfusion. The latter is a cross-species barrier in organ transplantation and is known as the main cause of human immune rejection of a donor pig's kidney. These antigens are present as glycoconjugates of different molecular configurations such as glycoproteins and glycolipids. The carbohydrate chains attached to either proteins or lipids serve as antigenic determinants. Some carbohydrate structures are composed of more than two different sugar residues and have further chemical modifications at specific positions. Such structures are called *complex carbohydrates*. They are systematically assembled by sets of enzyme systems via complex biosynthesis processes. The expression of blood group substances A, B, H, and Lewis (Le) appears to be developmentally and differentiationally regulated. Atypical expression of such substances may lead to the formation of tumor-associated antigens.

1.3 T-dependent and T-independent Antigens

Protein antigens fail to elicit antibody responses in athymic mice and *nude* (−/−) mice. Polysaccharides and other macromolecules with repetitive antigenic determinants can induce unimpaired antibody responses in these mice. These observations establish two broad categories of antigens, T-dependent (TD) and T-independent (TI). TI antigens are further divided into type I (TI-I) and type II (TI-II), based on the ability to elicit antibodies in the CBA/N mouse strain, with an X-chromosome linked immunodeficiency (*xid*). Lipopolysaccharides (LPS)

of gram-negative bacteria, which induce antibodies in such strains, are the TI-I antigens; capsular polysaccharides of gram-positive bacteria and exopolysaccharides that induce no response in *xid* strains are classified as TI-II antigens.

Glycoproteins are TD antigens; other forms of glycoconjugates, including glycolipids, Glycosphingolipids, glycosaminoglycans, and proteoglycans, are generally T-independent in nature. The carbohydrate chains of glycosaminoglycans and proteoglycans are composed of repeats of disaccharide units and are relatively large. Their antigenic reactivities may vary significantly among molecules and depend on the structure of a specific preparation and the animal species used for immunization. Glycolipids are a unique category of antigens since their hydrophobic lipid tails may integrate into cellular membranes of distinct cell types while the hydrophilic sugar chains are displayed on the surfaces. There are many documented examples to prove that molecules with such structural configurations are potent antigens and vaccines.

2
Diversity of Carbohydrates

2.1
Composition, Sequences, and Linkages

Carbohydrates are unique in their structural diversity. The structure of a sugar chain is determined by the composition and sequence of its sugar residues, as well as by their glycosidic linkages. This is different from nucleic acids and proteins that are synthesized linearly in cells with a single type of covalent bond to bridge their monomers. Carbohydrates can be linked together in multiple ways and can thereby generate different structures with identical residue compositions and sequences.

Monosaccharides are the basic building blocks of carbohydrate structures. They can be linked by means of either α- or β-anomeric linkages at each joining point, whereby the free hydroxyl on given monosaccharide links an adjacent monosaccharide (Fig. 1). Unlike proteins that are connected solely by a peptide bond, carbohydrates utilize many possible

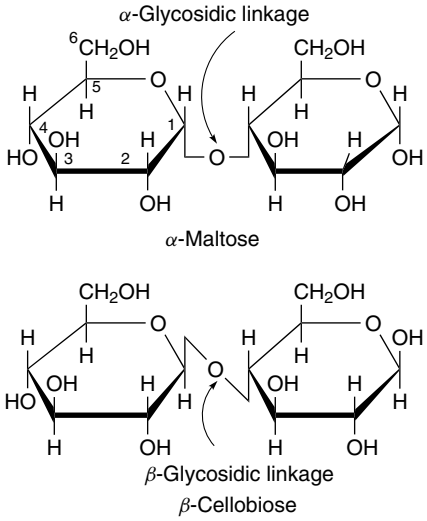

Fig. 1 α- or β-anomeric linkages of carbohydrates. The diagram illustrates the two kinds of linkages that may exist between at least two monosaccharides or sugar residues. These linkages may be either α- or β-anomeric where the free hydroxyl on one monosaccharide connects to an adjacent monosaccharide.

glycosidic linkages so as to extensively diversify their structures. Two amino acid residues, such as two alanines, can produce only one possible dipeptide; however, two molecules of glucose have the potential to generate 11 different disaccharides. A trimer of any of the 9 common sugar residues of the human body theoretically can give rise to 119 736 different structural isomers. This is strikingly in contrast to the maximal construction of 8000 tripeptides using 20 different amino acid residues. Theoretically, carbohydrate structures can have unlimited variation. This potential makes them well suited to provide various recognition signals.

Oligosaccharides and polysaccharides are composed of monosaccharides. A chain of 2 to 10 monosaccharide residues is called an *oligosaccharide*. A polymer of monosaccharides that is longer than the oligosaccharide chains of 10 to 20 sugar units in length is termed a polysaccharide. Usually, an oligosaccharide means also a structurally defined carbohydrate molecule. Polysaccharides are, however, large polymers of unspecified length with repeated structures. Oligosaccharides may be simply the shorter stretches or fragments of a polysaccharide. They could also be the sugar components of glycocojugates of diverse sources. The oligosaccharides attached to the glycocojugates of mammalian cells frequently consist of multiple distinct monosaccharide residues linked in complex structures and associated with different biological molecules. For example, the sugar chain structure of human blood group A substance differs in composition from that of group B or group H by only one monosaccharide residue (Fig. 2). These sugar structures may link to either a protein or a lipid molecule, forming a glycoprotein and a glycolipid, respectively.

Polysaccharide chains composed of a single type of sugar residue are termed *homopolysaccharides*. Those formed by more than one type of monosaccharides are named *heteropolysaccharides*. In a homopolysaccharide, the glycosidic bonds linking the monosaccharides are the only determining factor of their structural diversity. A well-documented example is

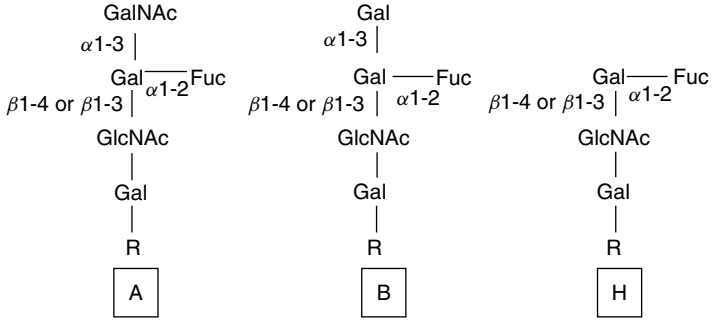

Fig. 2 Structures of human blood group A, B, and H. This diagram illustrates three different human blood group antigens A, B, and H. The addition of $\alpha(1\rightarrow2)$linked fucosyl residue to these oligosaccharides provides relatively rigid terminal branches. Within the A, B, or H blood group, the R group may be either lipid or protein. This kind of terminal branch is also found in other blood group substances such as the lewis (Le) sugar series, which are a family of fucosylated glycans (see also Fig. 5).

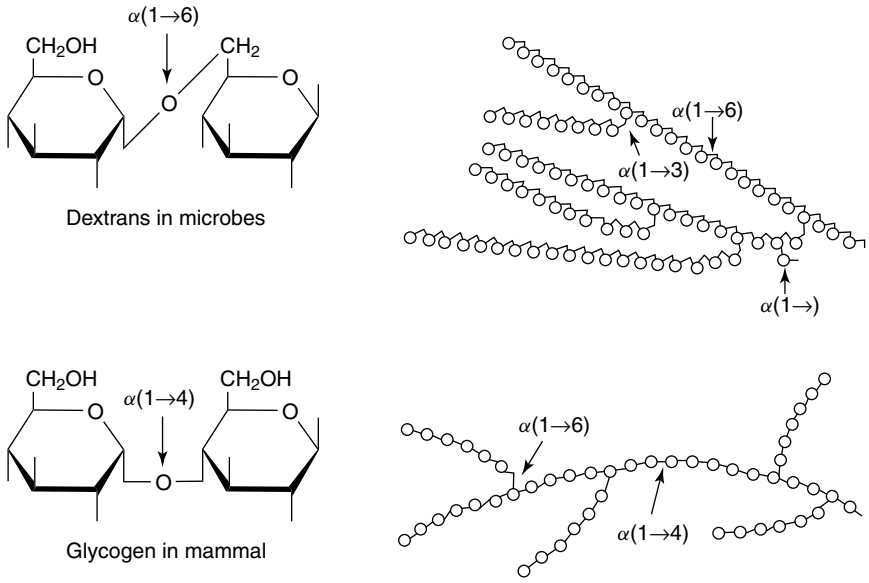

Fig. 3 Schematics of microbe's dextran and mammalian glycogen: linkages make the difference. The only source of structural diversity in homopolysaccharides is the glycosidic bonds linking the monoaccharides. This figure illustrates two commonly found polysaccharides – one in microbes and another in mammals. The polysaccharide with $\alpha(1\rightarrow6)$linkage is dextran, which is found in many bacteria including *Lactobacillaceae*. The polysaccharide with the $\alpha(1\rightarrow4)$ is glycogen and it is found in mammals as one of the energy storage biological molecules.

a class of polysaccharide called *dextrans* (Fig. 3). These macromolecules are composed entirely of glucose residues and are produced by numerous bacteria of *Lactobacillaceae*. However, dextran molecules derived from different strains differ significantly in their glycosidic linkage compositions. Some dextran preparations are predominantly or solely $\alpha(1\rightarrow6)$linked, forming molecules with dominantly linear chain structures; others are composed of multiple glycosidic linkages, including $\alpha(1\rightarrow6)$-, $\alpha(1\rightarrow3)$-, $\alpha(1\rightarrow2)$- and others, generating heavily branched molecules. These bacterial products and mammalian glycogen differ from each other only in linkage. Mammalian enzymes cannot digest dextrans as well as most microbial polysaccharides, and thus they may remain *in vivo* for a long period of time after an immunization. Linkage largely determines sensitivity or accessibility of polysaccharides to enzymes and, frequently, their antigenic reactivities. Branches occur in a polysaccharide when two or more C-atoms of one residue are involved in glycosidic linkage with other residues. Polysaccharides with more branches present more terminal structures.

Most heteropolysaccharides are composed of two or three different sugar residues and termed as *diheteroglycans* and *triheteroglycans*, respectively. The heteropolymers that consist of more than six distinct monosaccharides are rarely seen in living organisms. On the basis of the organization of sugar residues in heteropolysaccharides, they are further

classified as simple heteropolysaccharides and complex heteropolysaccharides. In the former, each polysaccharide chain is a homopolysaccharide, though two or more different homopolymers are present in a large heteropolysaccharide. In a complex heteropolysaccharide, the polymer contains two or more different types of sugar residues in a single branch.

2.2 Conformational Diversity

Conformational flexibility is an intrinsic property of carbohydrate molecules. An oligosaccharide in solution may exist in many different conformations with the lower energy forms predominating. Significant influence of the composition of glycosidic linkages on the structural characteristics of oligosaccharides and polysaccharides had been suggested for some time. In the 1960s, it was pointed out: ''It is important to remember that each glucose residue is free to rotate around the $\alpha(1\rightarrow6)$ glycosidic bond so that the schematic representation in Fig. 3 for isomaltose is not rigid. It may well be that the molecules prefer certain conformations in solution, conformations in which the planes of the ring bear a definite orientation to one another (see: Kabat, E.A., Structural Concepts in Immunology and Immunochemistry, Second Edition, Holt, Rinehart and Winston, New York, 1976, Page 21).'' In reacting with protein binding sites, however, certain conformations of an oligosaccharide may be selected and stabilized. Such phenomenon was later termed *induced fit*.

Recent technological advances have made it possible to ''see'' whether an induced fit indeed occurs when an oligosaccharide intereacts with its receptor. This can be achieved by comparing the solution conformers of oligosaccharides with those in carbohydrate–protein complexes. Nuclear magnetic resonance (NMR), fluorescence energy transfer (FET), optical rotation (OR), or Raman optical activity, can be applied for detecting the molecular flexibility in solution. X-ray crystallography gives high-resolution determinations of molecular coordinates in the ''frozen'' state. These comparative studies demonstrated that (1) $\alpha(1\rightarrow6)$ glycosidic bond in an oligosaccharide is more flexible than other linkages; (2) the linkages attaching terminal residues to main chain structures are more flexible; (3) those in internal chains are relatively stable; and (4) sugar rings are generally rigid in conformation, but, induced ring distortion can be seen.

The $\alpha(1\rightarrow6)$ glycosidic bond is superior to other glycosidic bonds in conformational flexibility since three torsion angles are required to define the conformation of this glycosidic bond (Fig. 4). Using NMR, the solution conformation of melibiose [Gal$\alpha(1\rightarrow6)$Glc] was compared with that in its complex with ricin B-chain. The disaccharide exists predominantly as two conformers, resulting from rotation about the $\alpha(1\rightarrow6)$linkage. Only one of the two conformers binds to the lectin. Enzymes may also recognize only certain conformations of their carbohydrate substrates. GlcNAc transferase V can use Man $\alpha(1\rightarrow6)$ Man for extending N-linked oligosaccharides into higher branched structures. To see which conformer is suitable for the enzyme, two rigid bicyclic analogs of Man $\alpha(1\rightarrow6)$ Man were generated by fixing the $\alpha(1\rightarrow6)$linkage in either a gauche–gauche (gg) or gauche–trans (gt) conformation. It was shown that only the gg conformer was used as substrate by the enzyme. Thus, this enzymatic selectivity depends on the conformational property of carbohydrate molecules.

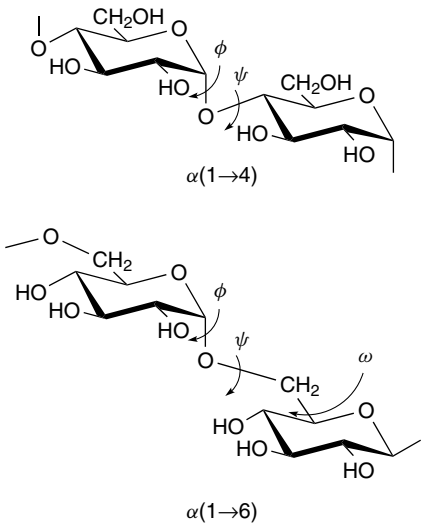

Fig. 4 Torsion angles of $\alpha(1\rightarrow4)$ and $\alpha(1\rightarrow6)$linkages. The glycosidic bond with the greatest conformational flexibility is the $\alpha(1\rightarrow6)$ glycosidic bond. Its flexibility is attributable to the fact that three torsion angles are required to define the conformation of this glycosidic bond.

The type of linkage also determines the chain conformation or the 3D structure of the intact polysaccharide. In polysaccharides, all component monosaccharides exist in the ring configuration, except for the terminal-reducing residue, in which there is equilibrium between the ring and its open-chain form. The geometry of the individual sugar rings in a polysaccharide is essentially rigid. However, adjacent monosaccharides are potentially rotatable around their glycosidic bonds. The range of rotation varies for different glycosidic linkages and is limited by steric hindrance between adjacent rings and by hydrogen-bonding patterns between groups in adjacent residues. Depending on sugar chain linkage types, homopolysaccharides may exist in four different conformations: the extended ribbon (Type A), the flexible helix (Type B), the crumpled ribbon (Type C), and the flexible coil (Type D). The fourth type has the most flexibility, as seen in $\alpha(1\rightarrow6)$ dextran. Differing from other glycosidic bonds, three torsion (rotational) angles, ϕ, ψ and ω are required to define the conformation of a $\alpha(1\rightarrow6)$linkage. Irregularities in composition and the existence of large branched structures can inhibit regular conformational patterns.

Oligosaccharides with terminal branches are relatively rigid in conformation. Such structures are frequently seen in alloantigens and serve as the key carbohydrate structures for immunorecognition. As shown in Fig. 2, addition of $\alpha(1\rightarrow2)$linked fucosyl residue in the linear sugar chains generates the terminal branch-type structures of human blood group A, B, and H. Terminal branches are seen also in other blood group substrances, such as the Lewis (Le) sugar series, which are a family of fucosylated glycans (Fig. 5). Sialyl Le^x is a ligand for E-selectin. Its solution conformation was studied using proton NMR to assign each proton and advanced NOE (Nuclear Overhauser Effect) measurements to determine inter-proton distances. Unlike other oligosaccharides with multiple conformers in solution, Le^x is predominantly in a single rigid conformation. The conformation of sulphated Le^a approximates also that of the unsulfated analog (Le^a). The enhanced binding of sulfated

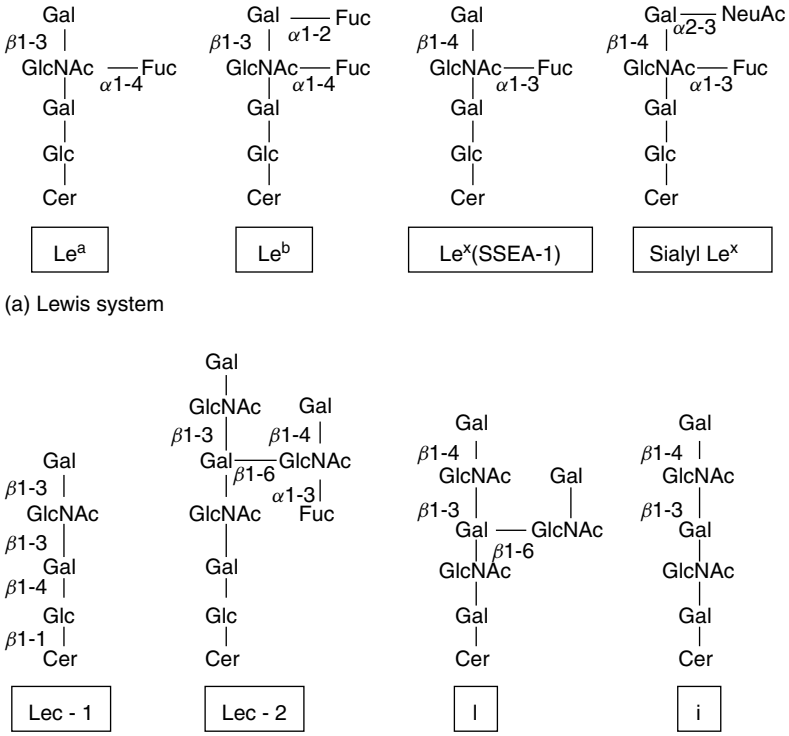

Fig. 5 Schematics of blood group substances I, i, and Le series. This diagram illustrates the rigid conformation of various terminal chain possessing oligosaccharides. Some sugar chains represented here have had $\alpha(1\rightarrow2)$linked fucosyl residues added to create the terminal branches of the human blood group substances. (a) Lewis (Le) sugar series. (b) I and i sugar chains.

Le^a to E-selectin was thus attributed to favorable electrostatic interactions between the charged sulfate group and the selectin molecules. Close packing between fucose and galactose residues might be a major cause of this conformational rigidity. Such conformational rigidity is also seen in other blood group substances.

Understanding the conformational flexibility or rigidity of oligosaccharides is important for the rational design of drugs, vaccines, and other biological reagents using carbohydrate molecules. Recent recognition of a conformational epitope of a sugar chain as an effective vaccination against meningococcal infections highlights this concept. Meningococcal meningitis is a severe childhood disease that often results in significant disability or death. Two major etiological agents of meningitis are the group B *meningococci* and capsular type K1 *Escherichia coli*. The virulence of these organisms is attributable to structural mimicry between their common $\alpha(2-8)$-polysialic acid capsular polysaccharide and human tissue antigens. This property allows the bacteria to evade immune

surveillance. Accordingly, such structural mimicry poses a challenge to the development of an effective vaccine to protect against this infection. NMR and other experiments found, however, that the capsular polysaccharide of the bacteria can adopt a unique ''antigenic conformation'' of helical structures, which are pathogen-specific and are not cross-reactive with the smaller oligomers of sialic acid expressed by human tissue. This led the way to design and develop chemically modified sugar chain vaccines, whereby the pathogen-specific polymer helical structures were better preserved. In an immunization using one of the compounds, N-propionylated group B meningococcal polysaccharide (NPrGBMP), the major population of antibodies elicited showed no significant cross-reactivity with $\alpha(2-8)$-polysialic acid, but preserved all bactericidal activity *in vitro* and protectivity *in vivo*.

2.3 Biological Complexity

By reviewing the chemical characteristics of carbohydrates, it is clearly seen that carbohydrate chains can have almost unlimited variation. The actual variation in carbohydrate structure in a given organism, is, however, restricted by the complexity of biosynthesis of carbohydrates. Sugar chains are not primary gene products. The biosynthesis of a carbohydrate chain is catalyzed step by step by a cluster of specific enzymes, called *glycosyltransferases*. For example, a cluster of genes directs the biosynthesis of the group B *meningococci* capsular polysaccharide (GBMP) that we discussed above. Each enzyme is responsible for a specific chemical reaction for the synthesis of the molecule. Glycosyltransferases are protein products of genes. For every new carbohydrate structure, a gene must be provided. It is, thus, believed that any given organism has a limited number of variations in carbohydrates. Carbohydrates are, however, the most abundant organic substances and are produced by virtually all the living organisms. They may employ various mechanisms and pathways for sugar chain synthesis. Thus, the overall repertoires of diversity and complexity of naturally occurring carbohydrate molecules can be extraordinarily large.

Bacterial polysaccharides are typically much more complex than those produced by plants or animals. They are often partially composed of unusual sugar residues that are rarely seen in higher eukaryotic species. Although only nine monosaccharides are commonly seen in mammals, over a hundred different monosaccharides are found in bacteria. Some of these sugars, such as ketodeoxyoctonic acid, were previously thought to be limited in their occurrence to LPS. Other interesting examples include the identification of hexosaminuronic acids in a wide range of bacterial polymers, aminohexuronic acid in *E. coli K7*, *Streptococcus pneumoniae* type 12 F and *Achromobacter georgipolitanum*; amphipathic exopolysaccharide ''emulsan'' from *Acinetobacter calcoaceticus*; and the presence of several *o*-methyl sugars, including an *o*-methyl-6-deoxyhexose, in the exopolysaccharide sheath. In addition to carbohydrates, the microbial polysaccharides contain various ester-linked substituents and pyruvate ketals, which are frequently of immunological significance.

Glycoproteins are present in both mammals and microbes. The prokaryotic microorganisms synthesize the N-linked and the O-linked oligosaccharides on proteins, just as mammals and other eukaryotes do. Their glycosylation machineries have,

however, significant differences. Prokaryotes lack internal membrane-bound organelles, such as a nucleus, endoplasmic reticulum (ER), and Golgi apparatus. They process oligosaccharides on the outside of the cell membrane in the so-called extracellular space. The sugar chains decorating the glycoproteins of microbes of various strains or species are quite diverse in their structures. Many of them are selectively or specifically expressed by certain strains and/or species. There are, however, instances where bacteria-produced oligosaccharides share similarity with eukaryotic sugar chain structures. As discussed above, a documented example is the structural similarity between the $\alpha(2-8)$-polysialic acid capsular polysaccharide of human pathogens and the sialic acid structures of human brain tissues. By mimicking host carbohydrates, the pathogen evades detection by the immune system, which recognizes it as part of "self." This has been recognized as a strategy by which a number of pathogens evade host immune recognition.

Microheterogeneity in carbohydrates is another documented phenomenon that can be attributed to the characteristics of sugar chain biosynthesis. Sharply contrasted with the template-dependent mechanism of nucleic acid and protein synthesis, there is no rigorous quality-control mechanism in the biosynthesis of sugar chains. A polysaccharide may thus not only have a main sugar chain composed of a type of repetitive structure but also contain a few different minor structural moieties as well. Immunologically, the former may form a dominant antigenic determinant of a polysaccharide. The latter may generate a minor antigenic determinant of the antigen.

3 Sugar Chains as Antigenic Determinants

As discussed above, microbial carbohydrate antigens of multiple structural configurations have been recognized. Polysaccharides and lipopolisaccharides are widely produced by many bacterial species. Glycoproteins are expressed and displayed on the surface of virions in almost all known viral species infecting mammals. Viruses take advantage of the cellular machineries of carbohydrate synthesis to produce sugar chains and glycoproteins. Parasites of mammals are higher eukaryote species and have their own enzymatic systems for the biosynthesis of carbohydrate molecules and protein glycosylation, generating diverse sugar structures. Presence of glycoproteins in some bacterial species has been also recently recognized. The oligosaccharide chains that define the antigenic specificities of these microbial antigens are their antigenic determinants.

3.1 Sizes of Antigenic Determinants

An antigenic determinant is a part of an antigen that is bound by and is complementary to the combining site of a specific antibody. It is the key element for host recognition and immune response. The antigenic determinants of a carbohydrate antigen are generally its oligosaccharide chains in certain size, shape, and conformation. Given this widely accepted definition, it is possible to estimate the size of a carbohydrate-based antigenic determinant by characterizing the specific interaction between carbohydrate ligand and its antibody-combining sites. The exact sizes and shapes of an antigenic determinant can be, however, visualized by

X-ray crystallographic characterization of its 3D structure.

A model system, $\alpha(1\rightarrow6)$ dextran and antidextran antibodies, was applied to address the question regarding sizes of a carbohydrate-based antigenic determinant. Native dextran N279 is a near-linear macromolecule of glucose with predominant $\alpha(1\rightarrow6)$linkage (90%). The relative structural simplicity of this carbohydrate antigen and the availability of oligosaccharides of $\alpha(1\rightarrow6)$linked glucose made it suitable for such studies (See Fig. 6). Sizes of antibody-combining sites were measured by competitively displacing the dextran from dextran–antibody complexes by various isomaltose oligosaccharides. The combining site is considered to be complementary in size to the smallest oligosaccharide giving maximum competition. Such an oligosaccharide is defined as the epitope or antigenic determinant. It may vary in size from a lower limit of one to two glucoses to an upper limit of six to seven.

3.2 Types of Carbohydrate Epitopes: Terminal and Internal Structures

A carbohydrate antigen may display both the terminal sugar moieties and internal chain structures on its solvent accessible surface. This is owing to the hydrophilic property of carbohydrates, making them strikingly different from proteins. In aqueous solution, proteins tend to fold to bring their hydrophobic side chains together, forming an oily core with polar side chains exposed. Surface moieties of a protein antigen may serve as antigenic determinants interacting with B-cell Ig-receptors;

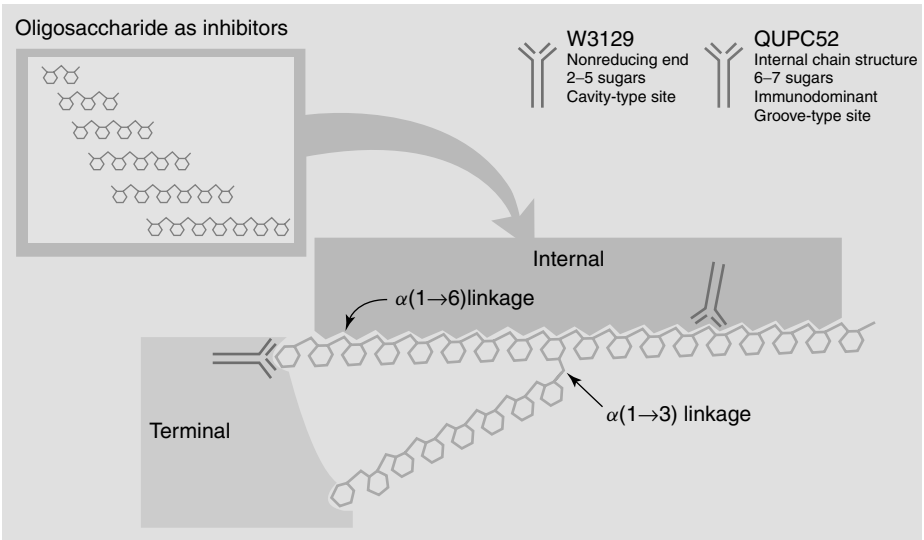

Fig. 6 Isomaltose oligosaccharides as ''rulers'' to measure the sizes of antigenic determinants. The diagram illustrates the two different specificities of anti-$\alpha(1\rightarrow6)$ dextran antibodies. Antibodies bound to polysaccharide-$\alpha(1\rightarrow6)$ dextran can be either cavity-type for terminal epitopes or groove-type for internal epitopes. The size of the antibody binding site can be determined by using oliogsaccharides of different number of sugar residues as competitive inhibitors that displace the dextran–antibody complexes.

interior residues are generally not accessible to such interactions. Carbohydrates are built up by monosaccharides whereby the enriched hydroxy groups readily interact with water molecules by hydrogen bonding. Their glycosidic linkages are more flexible than the peptide bonds in proteins and protein-like folding patterns are not seen in polysaccharides. Thus, not only are the terminals of the carbohydrate chains accessible for molecular recognition but residues in the internal chain are also exposed in solvent and are frequently reactive.

This important concept was first established in an immunochemical study focusing on the fine specificities of antidextran antibodies. Immunochemical mapping of the combining sites of two monoclonal myeloma proteins specific for $\alpha(1\rightarrow6)$ dextran, W3129 and QUPC52, established experimentally the existence of combining sites, which are specific for either the internal linear chain or the terminal structures of carbohydrate molecules (See Fig. 6 for a schematic view of their binding specificities). W3129 had a site saturated by isomaltopentaose, whereas QUPC52 accommodated isomaltohexaose. The binding constants were $1 \times 10^5\ M^{-1}$ for the former and $5 \times 10^3\ M^{-1}$ for the latter. Further analyses showed the terminal nonreducing glucose to contribute 50 to 60% of the total binding energy with W3129 but less than 5% with QUPC52. The two antibodies also differ in their ability to precipitate a synthetic linear dextran with about 200 glucoses. QUPC52 but not W3129 forms precipitins in saline. These observations were interpreted to indicate that the combining sites of QUPC52 must be a ''groove'' into which internal chain epitopes of $\alpha(1\rightarrow6)$linked glucose could fit; in contrast, the nonreducing ends of dextran may be held by the cavity-type site of W3129. Computer model building studies on two cavity-type mAb, W3129 and 16.4.12E, and one groove-type mAb 19.1.2 support the immunochemical distinction of these two basic types of combining sites. Recognition through either terminal moieties or internal structures of a carbohydrate molecule may also occur in other protein–carbohydrate interactions.

X-ray crystallography visualizes the epitopes bound in their combining sites. Such analyses have been performed on several carbohydrate–antibody complexes. The presence of terminal, branched terminal, and internal chain epitopes of polysaccharide antigens, as well as their corresponding antibody-combining sites, have been confirmed. The crystal structure of the murine Fab S-20-4 from a protective anticholera, Ab specific for the lipopolysaccharide Ag of the Ogawa serotype was determined in its unliganded form and in complex with synthetic fragments of the Ogawa O-specific polysaccharide (O-SP). The upstream terminal O-SP monosaccharide was shown to be the primary antigenic determinant to accommodate the antibody binding pocket. This antibody-combining site is immunochemically similar to a cavity-type anti-$\alpha(1\rightarrow6)$ dextran, W3129, in that a single terminal sugar residue accounts for 90% of the maximal binding energy. A *Salmonella* trisaccharide epitope bound by mAb Se 155-4 was also extensively studied. The Fab of this mAb was successfully cocrystallized with a branched trisaccharide αD-Galp$(1\rightarrow2)[\alpha$-D-Abep$(1\rightarrow3)]$-α-D-Manp. The trisaccharide fills a hydrophobic pocket, 8-Å deep by 7-Å wide, a size close to previous estimates of the minimum for anti-$\alpha(1\rightarrow6)$ dextran sites.

Unlike the above examples, whereby the terminal or branched terminal epitopes

was seen in crystallized carbohydrate antibody complexes, the crystal structure of a monoclonal Fab (YsT9.1.) and a *Brucella* A cell wall polysaccharide showed binding between a groove-type site and an internal chain epitope of microbial polysaccharide. It discriminates the *Brucella abortus* A antigen from the nearly identical *Brucella melitensis* M antigen. By forming a groove-type binding site, lined with tyrosine residues, this antibody accommodates the rodlike A antigen but excludes the kinked structure of the M antigen. This is consistent with immunochemical data that the binding site of this groove-type anti-Brucella A polysaccharide antibody can be optimally filled by a pentamer or hexamer of $\alpha(1\rightarrow2)$linked A polysaccharide. The size of this epitope is similar to that which accommodates to the groove-type anti-$\alpha(1\rightarrow6)$ dextran antibodies, but much larger than the cavity-type anti-$\alpha(1\rightarrow6)$ dextrans.

4
Carbohydrate-protein Interactions

The biological significance of the sugar chain's structural diversity depends on whether cellular machineries can recognize their signals. In fact, at least two large classes of proteins, lectins and antibodies, are present in living organisms and serve as specialized ''decoders'' to decipher the information content of sugar chains. Lectins and antibodies represent two distinct models of protein–carbohydrate interactions. The former is widely seen in the events of cell–cell interactions and cell signaling, but is also found in the innate immune systems as antimicrobe reactors. The latter is a specialized system of immune recognition and anti-infection response. Our main interest here is with the carbohydrate binding characteristics and their functional correlations.

4.1
Lectins

Lectins are a large class of proteins or glycoproteins that can specifically or selectively bind carbohydrates. They are, however, neither enzymes nor antibodies. A wide range of living organisms, from microbes to mammals, produces lectins. Apparently, they are conserved in evolution. According to species origin, they are classified into at least four categories, which include microbial lectins, plant lectins, invertebrate lectins, and vertebrate lectins. In the last decade, most attention has focused on vertebrate lectins. On the basis of the similarities in sequence homology and activity, vertebrate lectins are grouped into five subfamilies, including C-type (Calcium-dependent), P-type, S-type, I-type, and pentraxins.

The carbohydrate binding activity of a lectin is commonly described in terms of the monosaccharide specificity, as suggested first by Professor Y. C. Lee. Experimentally, a type of inhibition assay, such as agglutination inhibition, is performed to identify the monosaccharide that most effectively inhibits the reaction. Lately, disaccharides have been considered to be a better way to define a lectin's specificity. Most lectins are able to cross-react with a panel of sugar chains with a common terminal sugar residue.

X-ray crystallographic studies identified some common characteristics in the binding pockets of some lectins and anticarbohydrate antibodies. Aromatic amino acid residues appear frequently in carbohydrate binding sites of various fine specificities. Such residues are large and participate in

a wide variety of van der Waals and electrostatic interactions. The majority of crystal structures so far resolved are associated with a network of H-bonds, frequently with water molecules, in their combining sites. Such bound water molecules play important roles at the contacting interface between carbohydrate ligands and receptors. In addition, polyamphiphilic surfaces were identified in the interfaces of a number of carbohydrate ligand and binding sites. The presence of relatively rigid structures is required to produce amphiphilic surfaces in solution. Carbohydrate molecules with branched termini, such as many blood group substances, are favorable for the generation of such contact surfaces.

4.2 Carbohydrate-based Self/nonself Discrimination

In the higher eukaryotic species, carbohydrate molecules serve as recognition signals for the cell–cell communication that occurs in a living organism. Carbohydrates also play critical roles in mediating the interactions that occur between hosts and microbes. This raises an important question on how molecular and cellular mechanisms allow self and nonself discrimination on the basis of carbohydrate structures. As discussed above, carbohydrates are unique in structural diversity. The microbe-produced sugar chains are structurally different from those expressed by the host organisms and thereby recognized by the host immune system as ''foreign'' and elicit an antibody response. This antibody or B-lymphocyte-mediated machinery is specialized for immune defense. It is, however, no longer useful for cell–cell communication in a host since B-cell clones that produce self-reactive antibodies are generally prohibited in the development of an individual's immune system. The lectin-mediated recognition machinery plays important roles in cell–cell communication.

Some characteristic differences between the lectin-mediated and antibody-mediated model of carbohydrate-recognition have been identified. First, lectins seem to have lower binding affinity to carbohydrates than antibodies do. Second, most lectins recognize the terminal epitopes or terminal branches of carbohydrate antigens; antibodies are able to bind either the terminal or internal epitopes. Third, lectins recognize a specific pattern, such as clusters of sugar structures. Their selectivity in carbohydrate binding is heavily dependent on the topological distribution of carbohydrate ligands. By contrast, antibody binding to carbohydrates is generally less dependent on the topological distribution of sugar epitopes but strongly relies on its binding affinity. The so-called cluster effect is seen in many lectin–carbohydrate interactions in cellular systems. In fact, the genetic and molecular machineries for constructing high affinity antibody-combining sites are not present in lectin systems. Apparently, the two carbohydrate-recognition systems have evolved to be better suited for their respective cellular functions.

In invertebrates and many lower vertebrate species, there are no acquired immune systems, such as those including B-cells and T-cells as found in mammals. They depend on the innate immune systems to combat potential microbial pathogens. In fact, both invertebrates and vertebrates have a self/nonself pattern recognition innate immunity system, which is based on the detection of carbohydrates that decorate the surface of microbial pathogen. This machinery is

responsible for the initial recognition step in the first line of internal defense, which triggers the initiation of various pathogen-killing or inhibition machineries. These include agglutination, endocytosis by phagocytic cells, and the activation of protease cascades, resulting in clotting, melanization, or complement-mediated killing of the pathogen. A fucose binding lectin, called *fucolectin*, was demonstrated to be an immune-recognition molecule in invertebranes and vertebrates, such as the horseshoe crab (*Tachypleus tridentatus*) and the Japanese eel (*Anguilla japonica*).

5
Immune Responses to Microbial Polysaccharides

5.1
T-independency of Anti-polysaccharide Responses

Microbial polysaccharides are T-independent antigens. As illustrated in Fig. 7, a polysaccharide activates B-cells directly by cross-linking their membrane-bound immunoglobulins, the B-cell antigen receptors (BCRs). Cross-linking BCRs is sufficient to induce B-cell proliferation,

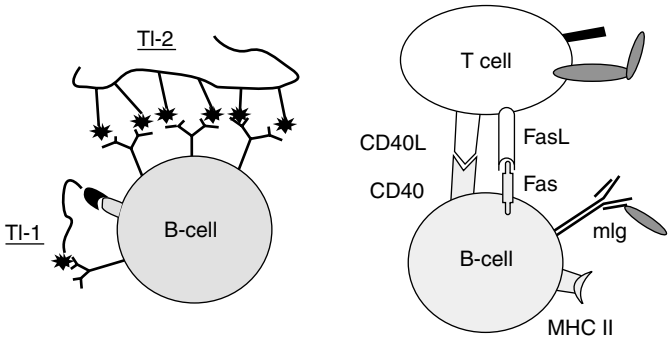

Fig. 7 Schematics of the TI- and TD-models of B-cell activations. The diagram demonstrates two distinct models of B-cell activation, the T-independent (TI) and the T-dependent (TD) models. (a) Both TI-I antigen (LPS) and TI-II antigen (polysaccharide) are able to cross-link the BCR (Ig) of B-cells and induce B-cell proliferation in the absence of T-cell help. TI-1 antigens (LPS) are polyclonal B-cell activators; TI-II antigens activate only the B-cells that express antibodies specific for given TI-II antigens. (b) TD protein activates B-cells in an antigen-specific and MHC-restricted manner. Unlike the TI antigens, protein antigens, in general, do not contain repeating structures and thereby are unable to cross-link the BCR (Ig) of B-cells on their own. Instead, specialized antigen-presenting cells, such as dendritic cells, macrophages, or B-cells themselves, take up protein antigens, process them in cells, and present the protein-derived peptides by their MHC class II molecule. Such peptide-bound MHC class II molecules are able to bind and activate CD4+ T-helper cells (Th) that express the appropriate T-cell receptor (TCR). Subsequent to the first initiation, additional molecular interactions, such as CD40 and CD40 ligand, and CD28/CTLA4-Ig with B7-1/B7-2, take place and activate further the interaction between T-B cells.

but not sufficient to induce class switching and antibody production. Secondary signaling is required for induction of class switching and for the terminal differentiation of B-cells into antibody-secreting cells (ASCs). This is significantly different from the B-cell activation by a T-dependent protein antigen.

B-cell activation via TD antigens is initiated by antigen-specific, MHC-restricted, T-cell–B-cell interactions. As a consequence of the first initiation, additional molecular interactions, such as CD40 and CD40 ligand, and CD28/CTLA4-Ig with B7-1/B7-2, can proceed. These molecular events further activate the interaction of T-cells and B-cells. The CD40–CD40 ligand interaction is particularly important in the TD antibody response. Blocking this molecular interaction also blocks the TD antibody response.

B-cells stimulated by TI and TD antigens may undergo different pathways of cellular activation and differentiation, that is, germinal center reactions and antibody-secreting cell responses. TD antigens induce both germinal centers (GC)s and ASCs. Many critical molecular and cellular events take place in GCs: clonal selection and differentiation of B-memory cells, IgH-class switching, somatic hypermutation and affinity maturation, and the production of precursors of ASCs. By contrast, most TI antigens induce an ASC response without GC induction. Thus, the typical TI-antigen response fails to induce memory cells, somatic mutation, and class switching (IgM to IgG). As a consequence, antibodies to polysaccharides and other T-independent antigens are generally in germ-line gene configurations without somatic mutations in their V regions. These antibodies were thought to be natural antibodies of relatively low affinity and are frequently isotype and idiotype restricted.

5.2 Complexity of Anticarbohydrate Responses

Given the structural diversity of carbohydrate antigens and the presence of families of cellular receptors with carbohydrate binding activities (lectins), the complexity of anticarbohydrate immune responses *in vivo* must be emphasized. This point was highlighted by a series of immunological studies on two microbial polysaccharides, $\alpha(1\rightarrow6)$ dextran (N279) and $\alpha(1\rightarrow3)\alpha(1\rightarrow6)$ dextran (B1355S).

Dextran B1355S and N279 are produced by different strains of *Leuconostoc mesenteroides*. Structurally, they differ only in their composition of glycosidic linkages. N279 is the simplest dextran with $\alpha(1\rightarrow6)$linked internal linear chains predominating; B1355S is the prototype of dextrans having significant proportions of non-$\alpha(1\rightarrow6)$linkages. Therefore, the tertiary structure of B1355S differs strikingly from that of N279. The predominant antigenic determinant of B1355S is the linear backbone of alternating $\alpha(1\rightarrow3)\alpha(1\rightarrow6)$linkages. $\alpha(1\rightarrow6)$ dextran has type D conformation, as a flexible coil in solution. However, by insertion of $\alpha(1\rightarrow3)$linkages into a $\alpha(1\rightarrow6)$linked linear chain, this structure may be completely altered. The backbone of alternating $\alpha(1\rightarrow3)\alpha(1\rightarrow6)$linkages is much more rigid than the $\alpha(1\rightarrow6)$ glycosidic internal linear chain.

When the two glucose-composed polysaccharides were used to immunize mice, distinct patterns of B-cell responses were induced. These include the repertoires of their specific antibodies and the pathways of splenic B-cell activation. $\alpha(1\rightarrow3)\alpha(1\rightarrow6)$ dextran elicits a highly restricted VHJ558/λ1 dominant response, while the $\alpha(1\rightarrow6)$ dextran responses are highly diverse. Moreover, unlike $\alpha(1\rightarrow3)$

$\alpha(1\rightarrow6)$ dextran, which induces only an ASC response, primary immunization with $\alpha(1\rightarrow6)$ dextran elicits both an ASC response as well as the GC reaction. In addition, $\alpha(1\rightarrow6)$ dextran but not $\alpha(1\rightarrow3)\alpha(1\rightarrow6)$ dextran is able to elicit an antigen-specific IgA response in a strain of mice that lack functional T-cells. This strain was generated by knocking out the genes encoding T-cell receptor β and δ, resulting in a complete deletion of T-cells in these animals.

Molecular and cellular mechanisms underlying the above observations are largely unknown. Polysaccharides of distinct physicochemical properties, showing characteristic patterns in their cellular compartment localization have been, however, recognized for some years. In the spleen, macrophages located in various cellular compartments were shown to retain polysaccharides selectively. Acidic polysaccharides were predominantly localized in red pulp macrophages; neutral polysaccharides were detectable exclusively or very intensely in macrophages of the marginal zone of the white pulp. Memory B-cells to T-dependent and T-independent antigens were found in the marginal zone. Follicular localization of some polysaccharides was shown to be complement dependent. Lipopolysaccharides (LPS) may interact with host cells in a number of diverse ways, as B-cell polyclonal activators or as T-independent antigen performing specific stimulations. The former is believed to be associated in their interactions with macrophages. Lipoarabinomannan of mycobacterial pathogens exhibits a wide spectrum of immunoregulatory functions, such as inhibition of interferon-mediated activation of murine macrophages, the scavenging of potential cytotoxic oxygen-free radicals, inhibition of protein kinase C activity, and evocation of a large array of cytokines associated with macrophages. This mycobacterial lipoglycan mediates the production of macrophage-derived cytokines, which, in turn, may evoke many of the clinical manifestations of tuberculosis and leprosy.

The above two dextrans are neutral polysaccharides but show differences in their cellular compartment localization. Dextran B1355S [$\alpha(1\rightarrow3)\alpha(1\rightarrow6)$ dextran] was detectable in splenic marginal zones of the white pulp, but not in GCs. Dextran N279 [$\alpha(1\rightarrow6)$ dextran] persisted, however, in both splenic germinal centers and marginal zone. Therefore, their corresponding B-cell clones were incubated *in vivo* in different microenvironments and were interacting with different types of cells, such as macrophages, follicular dendritic cells, and so on. Expression of lectin-like receptors by some of these cells has been recently documented. For example, mannose binding lectin (MBL) is expressed by some dendritic cells, which can bind dextrans. Involvement of distinct lineages or subtypes of B-cells is another important factor that may influence the pathway of B-cell activation in an immune response. Förster and Rajewsky demonstrated that in BALB/c mice, the dominant $\lambda1$ response to B1355S $\alpha(1\rightarrow3)\alpha(1\rightarrow6)$ dextran is derived, at least in part, from cells of the B-1 lineage. A broad repertoire of anti-$\alpha(1\rightarrow6)$ dextrans, associated with multiple V_H and V_L genes and solely with κ L chains, suggests, perhaps, that different lineages or subsets of B-cells are involved in anti-$\alpha(1\rightarrow6)$ dextran responses.

5.3 Delayed Maturation of Anticarbohydrate Responses

The delayed maturation of antibody response is a common characteristic of TI

antigens. The time required to develop full responsiveness to TI stimulations differs significantly among antigenic systems studied. In mice, antibody responses to TI-I antigens (LPS and other) and protein antigens reach adult levels within 1 to 2 weeks; antibodies to TI-II antigens can be detected only at 2 to 3 weeks. For pneumococcal polysaccharides SSS-III and dextran B1355S, full development of the antibody response is not reached until 4 weeks; with polysaccharides levan and $\alpha(1\rightarrow6)$ dextran, 7 and 13 weeks respectively are needed. In humans, children younger than 18 months fail to respond to microbial polysaccharides or produce antibodies at levels too low to be protective. Such poor responsiveness generally lasts until 5 years of age. Thus, there is a period when maternally derived protective antibodies have declined; yet the age-related development of immunity to bacterial infection remains immature. Pathogens causing severe problems during this high-risk period have long posed the need for developing efficient vaccines.

The underlying mechanism for the age delay in antipolysaccharide responses is still poorly understood. It has been illustrated that two distinct B-cell lineages/subtypes – B-1 and conventional B-cell – have different kinetics of B-cell development and functional maturation. It is interesting to see whether the delayed maturation of antibody responses to TI antigens coincides with B-1 or B-2 cell maturation. B-1 cell lineages (B-1a and B-1b) develop earlier than do conventional B-cells. By 4 weeks after birth, the mouse B-1 cell population approaches adult size and is able to mount a normal level of antibody response. Conventional B-cells reach maximal levels at 12 to 14 weeks of age. By comparing the kinetics of B-cell development and the timing of maturation of anti-TI antigen responses, it is clear that the delayed ontogeny of antibody response to some, but not all TI antigens, may be attributed to the time required for B-1 cell maturation.

However, an immunization strategy was successfully developed to improve childhood vaccination. Several important molecular events elicited by T-dependent antigens are lacking in the polysaccharide induced antibody responses, including memory cell induction, affinity maturation, and Ig H-chain class switching to IgGs. These events may occur in GCs of the peripheral lymphoid organs during T-dependent immune responses. Thus, efforts have been made to convert carbohydrate antigens into T-dependent antigens. Studies with T-dependent forms of $\alpha(1\rightarrow6)$ dextran, made by coupling isomaltose oligosaccharides to protein carriers, experimentally support this strategy. This conversion resulted in a significant shift in the age at which the maximum anti-$\alpha(1\rightarrow6)$ dextran was obtained. With native dextran (TI-II), mouse antibody responses reach adult levels in about 12 to 13 weeks; with the T-dependent form, the peak is at 3 to 4 weeks. V region sequence data and combining site mapping established that the T-dependent repertoire of anti-$\alpha(1\rightarrow6)$ dextran differs from the T-independent repertoire, indicating that distinct B-cell populations were elicited by the T-dependent conjugates.

Robbins and Schneerson (1990) introduced the conjugate strategy for human vaccination. By coupling purified capsular polysaccharides of *Haemophilus influenzae* B with tetanus toxoid, the first polysaccharide–protein conjugate against this bacterium was made. This conjugate vaccine has been applied in over 40 countries and is included in the Extended Program on Immunization of the World Health

Organization (W.H.O). Instead of large capsular polysaccharides, its oligosaccharide was conjugated with different protein carriers for vaccinations. Age-related shifting of antibody responses and Ig class switching to the protective IgG isotypes were observed with these vaccines, resulting in better protection of high-risk populations from *H. influenzae* B. Since these conjugate vaccines have become available, meningitis and other systemic *H. influenzae* B infections have virtually disappeared. The principles underlying the approaches to *H. influenzae* B vaccines have been extended to microbial polysaccharides of other bacteria, viruses, parasites, and so on.

6 Future Prospects

Recognition of carbohydrates as antigens began with the study of microbial polysaccharides. In 1917, Dochez and Avery found that when *Pneumococci* were grown in fluid media, there was a substance in the culture fluid that precipitated specifically with antisera to the same *Pneumococcus*. Heidelberger and Avery showed that this substance was a polysaccharide and not a protein, as previously thought. In the past few decades, a large amount of valuable information regarding the structural and immunological properties of various classes of carbohydrate antigens has been accumulated. In the new millennium, this field faces serious challenges as well as remarkable new opportunities.

The genome-sequencing project has reached a conclusion that only about 30 000 genes in the human genome must account for the complexity of the human organism. This finding emphasizes the importance of posttranslational protein modifications in modulating the biological activities of proteins and their cellular functions. Glycosylation is one of the most important protein posttranslational modifications, which introduces sugar chains of various structures to a newly synthesized protein molecule at given positions. Unraveling the biological roles of carbohydrate diversity attracts scientists from many scientific disciplines. An interesting analysis that appeared recently is about the possible contribution of carbohydrate chains to the neural network in the brain (Dr. Yoshitaka Nagai, Mitsubishi Kagaku Institute of Life Sciences). It is estimated that 10^4 synaptic contacts are present for a single neuron. The total number of neurons in a human brain is as large as 1.4×10^{10}. The information content of such a network system in the brain is, thus, estimated to be on the order of more than 10^{14}. This is far beyond the information carried by the human genome at the DNA sequence level, which is around the order of 3×10^9 to 10^{10}. Recent investigations using gene-targeting technology were able to generate animals with selective genetic defect. For example, a single glycosyltransferase can be targeted and destroyed. Several groups of scientists investigated such genetically engineered animals by all available means and from different scientific aspects. They systematically investigated not only the tissue expression of sugar chains but also the learning ability and behavior of an animal. Evidences obtained begin to suggest a link between specific glycosyltransferase and certain functional disorders in the brain. Perhaps, such comprehensive investigation reflects the characteristics of a new scientific discipline – glycomics or systemic glycobiology.

The worldwide epidemic spread of HIV infections and potential bioterrorism attacks have posed serious challenges to the entire scientific community. High-priority infectious agents that are current risks to our national security include multiple microbial pathogens. These agents are listed as category A, B, and C pathogens by the Center for Disease Control (CDC) of the United States. The genome-sequencing projects have uncovered the whole genome sequences of a number of human pathogens and are rapidly reaching completion of genome-sequencing for others. In the postgenomic era, it is important for us to learn to take advantage of the enriched genome sequence information, novel research concepts, and high throughput postgenomic technologies to benefit carbohydrate research. Professor Peng George Wang's group of Wayne State University has illustrated one of the excellent examples of such an effort. This group transferred genes of the Galactose biosynthetic cycle into an *E. coli* strain and was able to use this strain to produce Galactoside on a large-scale. Another example is, perhaps, the recent development of carbohydrate microarrays. In the year 2002, carbohydrate microarrays of different types were reported in scientific journals. In principle, these technologies are able to display a large repertoire of carbohydrates on a surface and thereby allow detection of a broad range of carbohydrate–protein interactions in a single assay. A platform of carbohydrate microarrays that was developed by the Columbia University Genome Center was designed to take advantage of the state-of-the-art technology of cDNA micoarray and to display different classes of carbohydrate antigens, including polysaccharide and glycoconjugates of different structural configurations. This technology has achieved the sensitivity to recognize the profiles of human anticarbohydrate antibodies with as little as a few microliters of serum specimen and reached the chip capacity to include the antigenic preparations of most common pathogens (~20 000 microspots per biochip). Substantial efforts must be made, however, to extend the repertoires of antigenic diversity and complexity of carbohydrate microarrays and to further improve the methods for chip production, microarray scanning, and data processing. Considerable bioinformatic efforts are also critically needed to enable the clinical application of diagnostic carbohydrate microarrays.

Acknowledgment

I am very grateful to Dr Shaoyi Liu, Dr Jose Morales, Ms Ellen Gluzman, and Mr Brian Trummer for their excellent technical assistance and many helpful discussions in preparing this manuscript and proofreading of this manuscript. This work was supported by grants from the National Institute Health and Compass Pacific, Ltd, to D. Wang.

Microgravity Analog Culture System (MACS)
Refers to the NASA series of bioreactors, including the rotating-wall vessel (RWV), slow turning lateral vessel (STLV), and the high aspect ratio vessel (HARV).

Modeled Microgravity
Analog paradigms of microgravity such as drop tower, suborbital rockets, MACS, parabolic flight, and so on.

Three-dimensional Cell Growth
Growth and assembly of cells into definite constructs with a third dimension.

T-cell Activation
The process by which T-cell receptor triggering leads to cytokine secretion and cell proliferation.

Microgravity affects cells and tissues either through direct response elements within the cell or by influencing the environment in which the cell lives. Cells respond to decreased gravity and the reordering of forces by changes in gene expression and cellular function. This review will address the unique attributes of microgravity that influence cell growth and function, progressing from ground-based models of microgravity, the cellular response to microgravity, and experimental results from cell experiments in microgravity.

1 Introduction

Microgravity is a unique environment in which cells, tissues, and organisms undergo novel adaptations. The adaptational responses provide insight into basic cellular mechanisms and, furthermore, provide opportunities in applied cell science. Investigations in microgravity and ground-based model systems have opened new vistas in tissue engineering, disease modeling, drug testing, vaccine production, and space cell biology. In microgravity, cells no longer sediment to surfaces, but rather freely associate with each other, forming large assemblies that can replicate in three dimensions. No doubt, the diminution of gravity from the cell culture setting allows the remaining forces to be more apparent. The rapid assembly and three-dimensional growth afford insight into the nature of physical forces that affect life at the cellular level and other new prospects in tissue engineering. Microgravity tissue morphogenesis produces functional three-dimensional constructs that are useful experimental models and may ultimately be amenable to transplantation. The reordering of forces in microgravity is reflected in the profound shape change, gene expression, differentiation, and metabolic alterations identified in space experiments. Despite the dramatic

response, cells not only survive, but also thrive to give a new perspective to biological systems.

2 Unique Cell Culture Conditions Offered by Microgravity

As life evolved on Earth, a multiplicity of physical and chemical factors invoked adaptations and participated in the complicated selection process. For many factors, there are clear examples of the role of physical forces in determining the pathways in evolution. A notable exception is gravity. The force of gravity has been constant for the 4.8 billion years of life evolutionary processes on Earth. Therefore, there is little or no anticipated genetic memory for terrestrial life to respond to gravitational force changes. As we transition terrestrial life to low gravity environments and study the adaptive processes in the cell, we will increase our understanding of gravity's role in shaping life on Earth.

The species on Earth evolved to perform various functions and processes in a gravitational force field of 9.8 m s^{-2}. Some gravity-dependent processes, such as balance and the ability of higher organisms to proceed along a surface, are obvious. Others, such as the directional growth of plants (gravitropism), are less obvious but are demonstrated through experimentation. For most species (microbial, plant or animal), only a small proportion of the functions influenced by gravity are known. During the past 40 years, the ability to achieve Earth orbit and experience long-term microgravity has created a need to understand the role of gravity in human, animal, and plant systems in preparation for exploration class missions into the solar system.

2.1 The Effects of Microgravity on Cellular Organelles and Cellular Function

Many biological stresses are induced by spaceflight and are visible in many areas of human physiology. The most dramatic response to spaceflight is the significant loss of bone and muscle mass and function, most likely caused by skeletal unloading and reduced activity. In addition, cephalad fluid shifting, neurovestibular disturbances, and a general malaise termed *space sickness* are experienced by astronauts soon after arrival in microgravity. In many instances, the basis of the negative influence of microgravity on human systems may be investigated using cell-based systems. This communication will offer a selected review of the past work at the cellular level and invoke models for testing in forthcoming opportunities on the International Space Station.

A major challenge in studying the adaptation of terrestrial life to space conditions resides in convincingly delineating the responses induced by microgravity from the radiation and stress experienced in spaceflight. Various *in vitro* parameters of immune function are suppressed in humans during and after returning from space missions. Exposure to cosmic radiation, along with physical and psychological stresses occurs concurrently with the microgravity of spaceflight. Understanding the effect of each of these factors in the physiological changes observed during spaceflight is a formidable challenge for space research programs (e.g. for immune function, which is affected independently by all three factors: microgravity, stress, and radiation).

It is unlikely that single cells can ''sense'' gravity through biophysical changes within the cell. Three theoretical approaches

address this problem and are reviewed by Cogoli and Cogoli–Greuter: (1) a direct effect: the direct interaction of gravity with one or more cellular organelles of a density different from that of the cytoplasm generates a pressure on neighboring structures (e.g. the cytoskeleton) and consequently a signal that is transduced into a biological event; (2) a nonequilibrium thermodynamic effect: the interaction of gravity with a few organelles is not sufficient to trigger one event, but a series of small changes is amplified to generate an important effect; and (3) an indirect effect: alterations in gravity induce changes in the microenvironment of the cell and the cell responds to the new environmental conditions.

Studies by Pollard suggest that in cells smaller than 10 μm in diameter, Brownian motion caused by impacts from molecules in the culture fluid are sufficient to counteract gravity-induced sedimentation. How much sedimentation can occur in cells larger than 10 μm is not known. Furthermore, this approach assumes that cells act like a bag of water containing solutes and undissolved particles (starch granules, oil vacuoles, and organelles). This theory does not agree with the observations that the aqueous phase of the cell is heterogenous, containing solution properties, colloidal regions, suspended and attached organelles, and contractile cytoskeletal structures. Studies by Nace suggest that organelles of the cell may impart significant torque on the cytoskeleton using the force of gravity. It is not known what effect the microgravity-related loss of this torque has on cellular physiology. Nevertheless, the possibility of a direct gravity sensor within mammalian cells exists although it is not known as yet.

The likelihood that gravity, a small force, would have an effect on cell function is questionable. The nonequilibrium thermodynamic effect, or the bifurcation theory, provides the reasoning to allow such small changes to exert a significant effect on biochemical processes of the cell. This theory, outlined by Mesland, argues that the biochemical processes of a cell are described in terms of nonlinear, nonequilibrium thermodynamics with chaotic outcomes. Therefore, the direction in which these reactions proceed is extremely sensitive to environmental conditions. This sensitivity may allow the seemingly small effect of gravity changes to have dramatic effects on cellular processes.

Microgravity can possibly alter the biophysical microenvironment around cells, and in turn, affect the shape, metabolism, and function of the cell. For example, the lack of sedimentation and thermal convection in microgravity leaves only simple diffusion and possibly surface tension–driven phenomena to move waste products away from the cell and bring nutrients toward the cell. Depending on the metabolic rate of the cell, diffusion and surface tension may not be sufficient to fulfill the metabolic requirements of the cell. These and other microgravity-induced alterations in the physical and chemical microenvironment alter cellular function.

3 Modeling Microgravity

Modeling microgravity for investigation of cell biological phenomena is a challenge that the space agency and scientists address in many familiar venues: parabolic flight, suborbital rocketry, drop towers, and neutral buoyancy. The former three strategies provide only short duration analog conditions, while the latter permits extended observations. A novel model emerged from early attempts to keep

cells suspended without invoking excessive hydrodynamic shear while providing abundant mass transfer. The rotating-wall vessel (RWV) bioreactors developed at NASA's Johnson Space Center (Fig. 1) model some aspects of microgravity and allow the extensive analysis of microgravity-related biological phenomena at the cellular level. We now refer to these culture vessels as the microgravity analog culture system (MACS). MACS is based on a previous clinostat design and consists of a zero headspace cylindrical culture vessel that rotates at a slow speed around a horizontal axis. These conditions compensate the gravity vector by rotation and create a solid body fluid rotation that can suspend cells or small particles in a sustained free fall condition, modeling conditions of microgravity for cell cultures.

This system provides us with the ability to assess function at a cellular level, without the potential confounding influences of psychoneuroendocrine factors. Furthermore, the cells are analyzed in real time while in analog microgravity in addition to a postflight or postanalog. Initially, the MACS demonstrated suppression of lymphocyte locomotion through collagen in ground-based experiments. Subsequent flight experiments conducted onboard Shuttle missions STS-54 and STS-56 confirmed suppression of lymphocyte locomotion suggested by MACS. This was

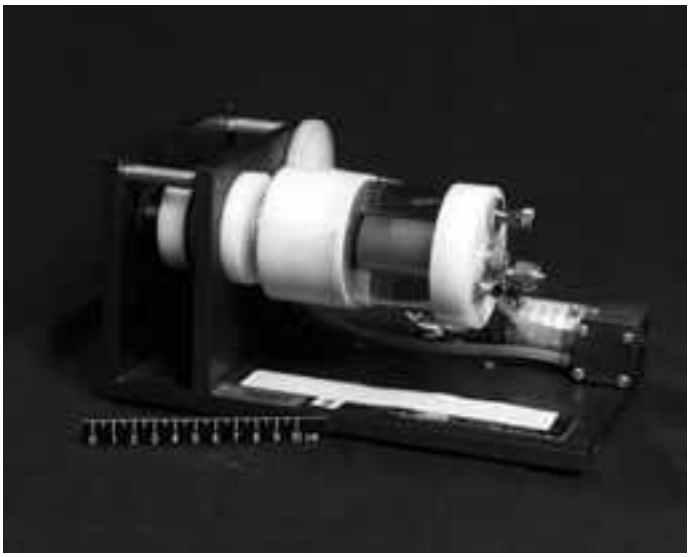

Fig. 1 The NASA rotating bioreactor allows for solid body fluid rotation. The growth medium completely fills the cylindrical vessel. Rotation of the vessel along its horizontal axis suspends the cells without stirring, randomizes orientation to the *g* vector, and renders cells to continuous fall at terminal velocity through the culture fluid. The cells have less interaction with inert surfaces and experience greater freedom for three-dimensional association. Several derivatives of the rotating bioreactor are available commercially (Synthecon, Inc.). The advantages lie in the low shear environment and the potential space analog condition.

a first in a series of experiments that demonstrated shared characteristics between orbital microgravity and rotational culture. The MACS provides for a unique opportunity to investigate the cellular responses as candidates for flight experiment opportunities. As with many models in science, a proportion of results are shared with the results from actual conditions in microgravity.

Hind-limb suspension is a common ground-based microgravity model used for experiments with rodents. Antiorthostatic suspension of rodents provides a 30° head-down tilt, unloading the hind limbs and weight bearing the front limbs. This position provides the cephalad-fluid shift observed in astronauts during spaceflight and mimics the arm-priority locomotion of astronauts. Studies in this model demonstrated organ-specific immune changes. Lymphocytes from lymph nodes and the peripheral blood of suspended animals had a reduced response to phytohemagglutinin (PHA) stimulation, whereas spleen cells of suspended animals displayed enhanced response. Other suspension experiments, as well as spaceflight studies, support this organ-specific response. In contrast, recent antiorthostatic suspension experiments reported enhanced responses in animals. Antiorthostatically suspended mice had enhanced resistance to primary infection and an enhanced protective immunological memory to *Listeria monocytogenes*. Mechanisms for this enhancement are not known, but the results indicate that both suspension and spaceflight cause complex immune alterations rather than a simple shut down of the immune system. Indeed, some effects are related to the altered orientation to gravity, while others may be the result of stress induced by the suspension model.

The effect of psychoneuroendocrine changes on immune-response studies is minimized by performing experiments on isolated cell populations in controlled culture conditions. Ground-based models of microgravity enable refining of hypotheses in advance of flight. The response of cells to microgravity is complex and difficult to identify if the cell is responding to the change in gravity or to a culture condition that is created by microgravity. In the former resides the posit that cells possess a ''gravity sensor.'' No one has as yet described a gravity sensor in mammalian cells, despite numerous studies demonstrating that mammalian cells respond to changes in gravity. In contrast, cells in the roots of plants have geotropic organelles that identify the direction of the gravity vector and promote root propagation that follows gravity.

Microgravity affects fluid systems such that there are no density-driven phase separations, no particle sedimentation, and no gravity-driven convection. Absence of these three conditions in cell culture results in a cell culture environment that is stressful or even hostile to many types of cells. In microgravity, and without facilitation, cell cultures rapidly become diffusion-limited, with regard to nutrient assimilation and waste-product dissipation. Therefore, the cellular response in microgravity may be related to these adverse culture conditions and not directly to microgravity.

Einstein described gravity in terms of a curvature of space–time in his theory of general relativity. In relation to biological systems, gravity is simply an acceleration force (9.8 m s^{-2} on Earth, G). Astronauts in orbit typically experience acceleration forces of 10^{-2} to 10^{-4} G. The force of gravity at the distance that most orbits take place in is practically the same as it is at

sea level. Microgravity is experienced by the astronauts because they are in free-fall around the planet. This is similar to the microgravity experienced during free-fall achieved in microgravity analogs conducted on Earth, for example, in drop towers (Fig. 2), parabolic aircraft (Fig. 3), and sounding rockets (Fig. 4).

To achieve the same level of microgravity by distance alone that is achieved by free-fall in orbit, the astronaut would have to be 17 times as distant from the Earth as

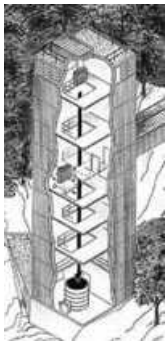

Fig. 2 Drop Tower. Drop towers offer a way to conduct 5- to 60-s microgravity analog experiments in free-fall. This analog is better suited for fluid characterization of the culture environment and rapid cellular events such as shape change and signal transduction.

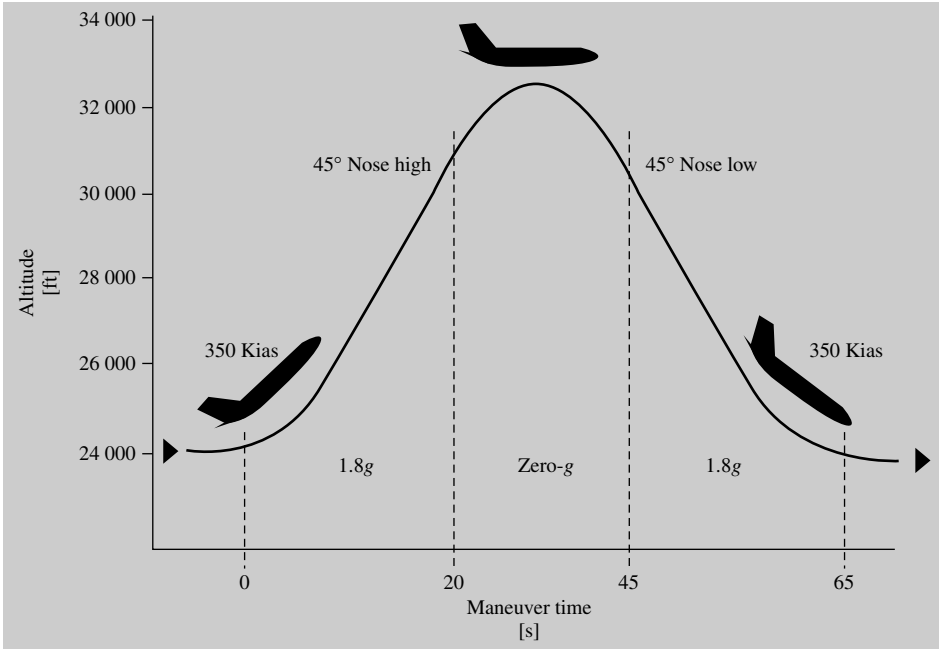

Fig. 3 Parabolic Flight. Parabolic flight, where a specially modified jet alternates steep climbs with long drops (much like a roller coaster), and generates 20 to 30 s of analog microgravity. A typical mission lasts 2 to 3 h and consists of 30 to 40 parabolas. Multiple parabolas are flown, allowing repeat experiments to be performed under the same conditions. Flight maneuvers can be modified to provide any *g*-force level less than 1.

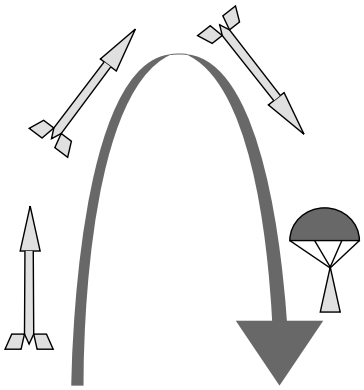

Fig. 4 Suborbital Flight. Suborbital rockets release a research payload at high altitude and offer 4 to 12 min of free-fall. Investigators can study cell movement, signal transduction, and characterization of fluid dynamics in the culture environment.

is the moon. Cell cultures can experience microgravity in space (orbit) or in models for simulating microgravity on Earth: clinostatic culture, parabolic flight (aircraft or sounding rocket), and drop towers. Drop towers only provide very short durations of microgravity (3 to 4 s) and are of limited use for biological experiments. Parabolic flight can provide somewhat longer durations of microgravity (aircraft: 15–35 s, sounding rocket: 7–15 min). Cell cultures can be maintained in clinostatic rotation indefinitely depending on the culture system used. Thus, there are analog systems that can be used to refine hypotheses for spaceflight. Each of these systems shares some characteristics with microgravity. It is essential to understand both the advantages and limitations of model systems. The main advantage for cell science is that many experiments can be modeled for extended periods on the ground using one or more of these analogs.

4 Cellular Response to Microgravity

More than 120 experiments have been performed in space during the past 15 years that demonstrate that microgravity induces changes in single cells. The opportunity to conduct experiments using cells in microgravity and the development of ground-based models provide *in vitro* models to study adaptation to the conditions in microgravity. Cellular responses to microgravity are varied, depending on cell type and species of origin. Lymphocytes from humans, monkeys, and rodents are affected by gravitational unloading. The list spans from the plant kingdom all the way across the animal phyla. The different parameters affecting cells seem to depend on their size, dynamics, shape, circadian rhythms, function, location, and so on. Mammalian cells are especially susceptible to microgravity-related perturbations. In the immune system, there is extensive evidence that microgravity suppresses the immune function *in vitro* and possibly *in vivo*. The outcome of the suppressed functions in long duration space travel is unknown. Nevertheless, it is of concern that widely accepted parameters of immune function are compromised in microgravity. The underlying mechanisms of dysfunction in microgravity are the subjects of flight and ground-based experiments.

4.1 Signal Transduction in Microgravity

An important phase of the microgravity-induced perturbations in transmembrane signaling is selective and not random. Most cells adapt to the new signal motifs and are able to survive. Several studies, beginning with Spacelab D-1 in 1985, SLS-1 in 1991, IML-1 in 1992, IML-2 in 1994, STS-55, -56, and many sounding rocket experiments from the mid-1980s to the mid-1990s, attest to the ability of cells to adapt to change induced by microgravity environments. The flight experiments, and ground-based studies using microgravity analog culture, suggest that single cells are sensitive to changes in gravity, as reflected by proliferation, gene expression, locomotion, and receptor-mediated signal transduction and differentiation.

Mammalian immune performance is critically tied to the function of thymus-dependent (T) lymphocytes. A hallmark of immune performance is the response of T-lymphocytes to activation through cell-surface receptors. The first *in vitro* T-cell activation experiments were performed aboard Spacelab 1 in 1983 by Cogoli et al. (Table 1). Results showed a dramatic suppression of T-cell activation in response to the widely used polyclonal activator, Concanavalin A. Spacelab D1 in 1985 and Spacelab SLS1 in 1991 continued the investigation of T-lymphocytes. The experiments confirmed the inhibition of T-cell activation in microgravity and raised the possibility of direct and indirect effects of gravity unloading on the T cells. The first signal required for T-cell activation is the presentation of antigen by the antigen-presenting cell, which activates a G-protein and phospholipase C. In the SLS-1 flight, it was found that production of the cytokine interleukin 1 (IL-1) expression was impaired in the monocytes. Interleukin-1 is a second signal that is necessary for T-cell activation. The subsequent signal to achieve full T-cell activation is the synthesis of the cytokine Interleukin 2 (IL-2) and the expression of its receptor (IL-2R). The first signal of antigen presentation is modeled *in vitro* using Concanavalin A (a plant lectin) that binds to saccharide groups on the T-cell antigen receptor. An interesting observation from this study was that the binding of Concanavalin A to the cell membrane and subsequent events, such as capping and patching of membrane proteins, were not altered in microgravity. SLS-1 experiments showed that monocytes present in the preparations flown did not release Interleukin-1 (IL-1). Therefore, it was hypothesized that the reason for the inability of T cells to activate in microgravity was the absence of IL-1 production by monocytes and hence, absence of the accessory signal. However, the production of interferon-gamma (IFN-γ) was slightly but significantly restored. The receptor for IL-2 was secreted in adequate amounts in lymphocyte supernatants in microgravity. Importantly, the absence of activation was not due to a lack of cell–cell contact.

It is known that spaceflight conditions and microgravity *per se* alters immune function. Indeed, the altered immune function may be the summation of the individual influence of stress (psychological and physical), cosmic radiation, and microgravity. Thus, the space environment may affect immune performance either directly, because of microgravity-induced changes or indirectly, through the stress related to performance and confinement. Therefore, interpretation of spaceflight studies on immunity must delineate the direct and indirect effects of microgravity on cells from the other factors associated with spaceflight.

Lymphocyte locomotion through interstitium is a critical stage in the immune response to antigenic challenge. Initially, the MACS was used to demonstrate the suppression of lymphocyte locomotion through collagen in modeled microgravity. Locomotion can be investigated *in vitro* using gelled type I collagen as a test matrix. In analog culture, lymphocytes completely lose their capacity to randomly locomote in gelled collagen.

Experiments conducted in microgravity onboard Shuttle missions STS-54 and STS-56 demonstrated similar suppression of lymphocyte locomotion and support the relationship between orbital microgravity and analog culture.

In a study by Cooper and Pellis, the MACS was used to further characterize the suppression of polyclonal activation of T cells with PHA (phytohemagglutinin). Results suggest that accessory cell costimulation in the form of cytokines is intact in the MACS. Furthermore, the calcium-signaling pathway may be intact during PHA stimulation in the MACS. Therefore, signal transduction mechanisms between T-cell receptor engagement and downstream protein kinase C (PKC) activation are sensitive to modeled microgravity. The suppression of lymphocytic PHA response is observed in both the lymphocytes of astronauts after spaceflight and in *in vitro* experiments in spaceflight and modeled microgravity. Although some studies suggest there may be a microgravity-induced PKC defect, T cells were fully activated to proliferate in modeled microgravity by direct activation of PKC using phorbol myristate acetate (PMA) and ionomycin. These pharmacological agents bypass mechanisms at the cell surface and impart their effect inside the cell: PMA by mimicking 1, 2-diacylglycerol (DAG) and activating the serine/threonine kinase PKC; ionomycin by increasing the cytoplasmic-free calcium ion concentrations. The ability to activate T cells in the RWV with PMA and ionomycin implies that all the cellular mechanisms involved in T-cell activation downstream of PKC activation and calcium ion flux are intact in modeled microgravity. Some flight studies indicate that PKC may be unaffected or activated by microgravity. It is still unclear as to how PKC is affected by microgravity and this requires further investigation. These results explain why PHA responsiveness could be partially restored by preincubating PHA-stimulated cultures at normal gravity before exposing them to modeled microgravity. Cells that achieved PKC activation and calcium flux continued on to proliferate even when they were exposed to modeled microgravity. Since PKC activation and calcium flux occur quickly after receptor triggering, one might expect full activation to be restored by advance exposure to PHA cultures. Although these events do occur within minutes, sustained receptor triggering of up to 48 h is required for optimal lectin activation. Once PHA primed cultures were exposed to modeled microgravity, the signal from the receptor was no longer sustained owing to the microgravity-induced lesion somewhere upstream of PKC activation that was observed with the phenomenon of suppression of lymphocyte locomotion in microgravity and modeled microgravity. In addition to polyclonal and oligoclonal models, antigen-specific models of T-cell activation are also suppressed in microgravity and its cell culture analog.

Currently, the results strongly suggest that signaling pathways upstream of PKC are affected in microgravity. An emerging hypothesis is that the microgravity-induced lesion in T-cell activation and lymphocyte locomotion resides between the cell surface and PKC. There is some

reflection of effect on PKC *per se*. Microgravity culture differentially alters the translocation of individual PKC isoforms in monocytes and T cells providing a partial explanation of adverse effects on T-cell activation. A significant variation in the intracellular distribution and quantity of PKC according to *g* levels was also observed in monocytes and peripheral blood lymphocytes aboard a Biorack experiment. These experiments demonstrate the sensitivity of PKC expression to gravitational force. There is no clear demonstration that the PKC changes are a direct consequence of variations in gravity or an indirect outcome of upstream changes as the cell adapts to the new physical environment. Commensurately, a marked decrease in the expression of the calcium-independent PKC isoforms, PKC-δ and PKC-ε, was described in human lymphocytes exposed to modeled microgravity culture. Functional association in microgravity may be determined by specific blocking of PKC isoforms expression followed by assessment of T-cell activation and locomotion both in microgravity and cell culture analog.

Microgravity experiments have been performed on several different mammalian cells. Flight experiments included HeLa cervical carcinoma cells, A431 human epidermoid carcinoma cells, and various immune cells, including primary isolated peripheral blood leukocyte populations and the transformed cell lines of Jurkat leukemic T cells and monocytic THP-1 cells. While HeLa cells proliferate normally in microgravity during orbital flight, other studies revealed responsiveness to hypergravity. At 10, 35, and 70 G in a centrifuge, HeLa cell proliferation and c-*myc* expression were significantly increased. Subsequently, HeLa displayed increased inositol 1, 4, 5-triphosphate (IP_3) levels and decreased cAMP levels. Studies with A431 cells examined the inducible expression of the transcription factor c-*fos*. In both clinostat and sounding rocket studies, the expression of c-*fos* was suppressed when induced by epidermal growth factor (EGF) or phorbol ester but not when induced by a calcium ionophore, A23187, or by forskolin, an activator of protein kinase A (PKA). Conversely, the EGF induced expression of c-*fos* in hypergravity (10 G) was slightly increased. The studies with A431 cells demonstrate that alterations in gravity have specific impacts on signal transduction mechanisms. Experiments with Friend murine erythroleukemic virus transformed cells, WI38 human embryonic lung cells, hamster kidney cells, and L8 rat myoblast cells, demonstrate normal proliferation and growth in microgravity. Thus, despite changes induced by microgravity, many cells adapt and proceed with many functions (i.e. proliferation still intact). In cultured liver cells, formation of multidimensional tissue-like spheroids from primary human liver cells was observed in modeled microgravity. These spheroids were composed of hepatocytes and biliary epithelial cells that arranged as bile duct–like structures along newly formed vascular sprouts.

Several studies addressed the ability of proteins and other macromolecules to interact with each other in microgravity. The binding of (1) EGF to receptors on rat osteosarcoma cells; (2) EGF to and the clustering of EGF receptors on A431 cells; (3) lectin to rhizobia; (4) alpha-fetoprotein to immobilized monoclonal antibodies; and (5) Concanavalin A to lymphocytes were all normal in microgravity. Thus, normal protein–protein interactions occur in microgravity.

5 The Experience in Microgravity

Microgravity and randomized gravity facilitate spatial colocalization and three-dimensional assembly of cells into large aggregates. It is believed that diminution or nullification of gravity results in other forces displaying dominance. More than 25 types of cells have been flown in space. For 20 years, flight experiments have shown that single cells respond to space conditions with changes in cellular morphology and function. Cytoskeletal reorganization occurs early after achieving orbit. Human dermal fibroblasts displayed a significant increase in collagen synthesis aboard Space lab. This might facilitate larger or more differentiated organoids by cell aggregation. Space flight decreases the amounts of osteocalcin and pre-pro-alpha 2 chain of type 1 precollagen mRNA in long bone and calvarial periosteum of rats. Hence, cell types adversely affected in microgravity (such as muscle, bone, and cartilage) may yield inferior types of tissue morphogenesis. Space bioreactors were used for a 137-day cell culture on Mir to generate three-dimensional cartilaginous constructs from chondrocytes, which were preaggregated on resorbable polyglycolic acid scaffolds. In parallel control experiments, the constructs were maintained in analog culture for the same period. In both flight and control cultures, chondrogenesis occurred, yielding many of the histochemical characteristics of native collagen. Flight constructs were mechanically inferior to constructs grown on earth, largely due to a disproportionate loss of one of the matrix components, glycosaminoglycan. Cartilaginous constructs obtained in the modeled microgravity

Tab. 1 Partial list of cells and tissues cultivated in microgravity in space and on the ground.

Cell/tissue	*Environment*	*Observation*
Lymphocytes	Several shuttle missions, Maser sounding rockets	Inhibited locomotion, Impaired immunocompetence, impaired mitogenicity, changes in cytokine production, altered cellular signaling
Chondrocytes	RWV in space (MIR/STS-79 for 4 months)	In space culturing of pre-assembled 3-D aggregates results in constructs which are mechanically inferior to similar aggregates grown in RWV on the ground. Effect might mimic microgravity-induced loss of cartilage
PC12 cells	Six weeks serial passaging of cells in culture bags on MIR Space Station (STS-86)	Establishes feasibility of long term, serial passaging of cells in space, formation of large aggregates with epitheloid morphology
MIP 101 colon carcinoma cells	EDU-1 on STS-70	Increased proliferation, enhanced carcinoembryonic antigen (CEA) production
Osteoblasts	Four days on STS-56 in Materials Dispersion Apparatus minilabs (MDA)	Inhibition of growth, reduction in serum growth activation, changes in microfilament structure

Tab. 1 (*continued*)

Cell/tissue	***Environment***	***Observation***
Myoblasts	Ten days on STS-45 in space Tissue Loss Flight Module "A" (TLMA)	Several permanent phenotypic alterations, including failure to fuse into myotubes
Neonatal rat heart cells	HARV	3-D organization, synchronous beating, isolated heart cells reestablish structural & molecular phenotypes of heart tissue
Rodent skeletal muscle satellite cells	HARV/STLV	Enhance proliferation, 3-D organization, attenuation differentiation
MIP 101 colon carcinoma cells	STLV	Increased proliferation, enhanced carcinoembryonic antigen (CEA) production
Human Ovarian Tumor Cells	STLV	Capability of growth out of the body, organization into differentiated tissue-like constructs, enhanced oncogene expression
Diverse human tumor cell	HARV	Organization of tissue-specific epitheloid structures, enhanced production of cell adhesion molecules
Human prostatic cancer cells	STLV, HARV	Enhanced differentiation, reduced proliferation in 3-D aggregates. Upregulation of growth factors and basement membrane proteins in co-cultures mimic physiological growth conditions of prostate epithelial cells with stromal cells, altered responses to sex hormones and growth factors
PC12 cells	STLV, HARV	Formation of large aggregates exhibiting neuroendocrine differentiation, altered cellular signaling mechanisms
Normal human kidney cells	STLV	Re-expression of tissue-specific morphology (microvilli) and differentiation markers
Bovine cartilage	STLV	Macroscopic large 3-D constructs with enhanced tissue-specific differentiation (ECM proteins e.g., chondroitin sulfate, and cytoskeletal proteins [e.g. vimentin])
Murine osteoblasts	Clinostat	Decrease of differentiated phenotype (reduction of alkaline phosphatase and osteocalcin)
Lymphoid tissue HIV	HARV	Repopulation of human tonsil fragments with exogenously added T and B lymphocytes; capable of infection by HIV
Liver	HARV	Expansion of tissue from microscopic fragments, angiogenesis

environment of the MACS were more similar in composition and mechanical strength to natural cartilage. This experiment demonstrated the microgravity effect on cellular functions and processes in the synthesis, secretion, and assembly of extracellular matrix proteins. It is known that microgravity exerts deleterious effects on existing cartilage and bone. This investigation demonstrated the effect that microgravity may have on remodeling of tissues such as cartilage. Earth-grown constructs in the analog culture were superior to the flight effects of 1*g*. Subsequent experiments should delineate the effects of *g* forces on the process of tissue morphogenesis.

Space cell culture may not offer advantages in tissue morphogenesis for all cell types. Experiments with osteoblasts (i.e. bone-forming cells) were performed on STS-56 to assess the gene expression changes that occurred in microgravity. The results were that prostaglandin synthesis did occur during space flight and there were significant changes in cellular morphology and the acting cytoskeleton. Additionally, there was reduced growth of osteoblasts after four days in microgravity. Following this, a series of experiments on the European Space Agency Biorack (STS-76, STS-81, and STS-84) were performed on osteoblasts using ground and in-flight 1*g* controls. The expression of immediate early genes such as c-*fos*, and *cox-2* was altered significantly in microgravity. However, osteoblast fibronectin mRNA, protein synthesis, and matrix remained unchanged after exposure to microgravity. This suggests the possibility of altered signaling in the osteoblast, since the expression of these genes is critical for gene transcription and cell activation. The aggregation and secretion of bioactive products in MIP101 colon carcinoma cells were enhanced in microgravity. The extent of aggregation, proliferation, and differentiation of PC 12 pheochromocytoma (neoplastic adrenomedullary) cells in space was also enhanced. In addition, the rate of glucose consumption was five times higher than in ground cultures.

Primary cultures of human cortical renal epithelial cells were flown on the space shuttle to test the hypothesis that the adaptation of cells to conditions in space is reflected in the changes in gene expression. Cells in microgravity and ground-based controls were grown for six days and fixed. RNA was extracted, and automated gene array analysis of the expression of 10 000 genes was performed. A select group of 1632 genes was regulated in microgravity. The magnitude of the response signifies that the conditions in spaceflight offer a multitude of perturbations to the cells and some of the motifs are coincident with known response suites. These were consistent with shear stress response genes and heat shock proteins. In other instances, there are gene expression changes that may be reflective of novel suites that may be related to microgravity, culture conditions, and changes in other forces such as convection. Finally, some are most likely related to the promotion of tissue morphogenesis. These included the Wilm's tumor zinc finger protein and the vitamin D receptor expressed in space cultures of differentiated renal cortical cells.

6 Conclusions

Microgravity thus affects cells in different ways. In bone and muscle systems, microgravity exposure results in inhibition

of cell function, while in others there is an encouragement of three-dimensional cell aggregate formation and secretion of bioactive products. Cellular mechanotransduction properties change, as does transmembrane signaling. These changes are more often than not selective. Across phyla from plant cells where subcellular responses, cell division, and growth and development are altered to bacterial virulence, which is enhanced in the case of *Salmonella typhimurium*, microgravity has multiple effects. In mammalian cells, cytoskeletal distortion is probably one of the major methods by which a cell initiates response to microgravity. In plant cells and in microbes with cell walls, the mechanism may be substantially different. The whole organism, cell or tissue could possibly act as a gravity sensor as opposed to having individual gravity sensing subcellular organelles. The concept of *tensegrity* offers a focus on mechanical energy at specific points and allows testing of hypotheses of how changes in gravity translate into a cellular response. Gene expression changes are also profound indicating the magnitude of gravity in the adaptational responses in cells in space. Genomic and proteomic analysis of different cells on the ISS will greatly enhance the existing knowledge. Utilization of simple, defined, and well-studied model systems such as *Escherichia coli*, *Caenorhabditis elegans*, *Drosophila melanogaster*, pisceans, and amphibians will also provide insight into microgravity effects on many fundamental processes as they transcend the cell to tissues, organs, systems, and organisms. Microgravity as an experimental tool has gained impetus, and with the establishment of the ISS and reliable ground-based analogs, microgravity will provide new inroads into cell biology.

Keywords

Adherens Junction
Cadherin-mediated cell–cell junction that attaches to the actin cytoskeleton thereby providing strength to the junction and allowing the cells to act as a single structure.

Cadherins
A family of single pass transmembrane proteins possessing five homologous domains in the extracellular region. Cadherins on adjacent cells bind in a homophilic, calcium-dependent manner to form a cell–cell junction.

Desmosome
A ''spot weld''-like cell–cell junction characterized by a dense plaque on the cytoplasmic face of the plasma membrane into which intermediate filaments attach. Mediated by members of the cadherin family, this specialized junction has tremendous cell–cell adhesion strength and is found in tissues that require strong cell–cell attachment such as the heart and skin.

Extracellular Matrix
An insoluble meshwork of cell-secreted macromolecules (including polysaccharides, such as glycosaminoglycans and large proteins, such as collagen and fibronectin) that holds cells together in tissues, and tissues together in organs, and also provides an adhesive substrate for cells that regulates cell behavior.

Focal Adhesion
A specialized cell-ECM junction where there is tight association between the cell and an ECM protein, such as fibronectin. Adhesion is mediated by the direct binding of

integrins to the ECM protein. Adhesion is strengthened by the transmembrane association of integrins with intracellular proteins that link the adhesion site to actin stress fibers within the cell's cytoplasm.

Hemidesmosome
A specialized cell-ECM junction that mediates very strong adhesion between the basal layer of stratified epithelia and the underlying basement membrane. The $\alpha_6\beta_4$ integrin functions at hemidesmosomes as a transmembrane link between the basement membrane and cytoplasmic proteins that link hemidesmosomes to the intermediate filament cytoskeleton.

Integrins
Heterodimeric transmembrane proteins containing one α- and one β-subunit. Integrins are generally known for their ability to bind ECM proteins; however, some integrins bind soluble ligands and/or counter receptors on other cells. Although integrins are known as adhesion receptors, they also function as signaling receptors that regulate cell behavior.

Tight Junction
A cell–cell junction that acts as a barrier to the passage of solutes between epithelial and endothelial cells and serves as a fence to prevent the movement of proteins within the plasma membrane from passing between the apical and basal surfaces of the cell layer.

A critical component in the development and homeostasis of higher eukaryotic organisms is the adhesion of cells to each other and to large insoluble proteins that form the extracellular matrix (ECM). These adhesions are referred to as cell–cell and cell–matrix junctions respectively. Specific families of cell surface transmembrane receptors connect these junctions with the cell's cytoskeleton. Three different cell–cell junctions promote the stable adhesion between cells: tight junctions formed by the claudin family, and adherens junctions and desmosomes both mediated by members of the cadherin family. Members of the integrin family function at cell–matrix junctions. A subset of integrins also mediate cell–cell adhesion events that are important for the immune response. In addition to providing structural linkages important for tissue architecture, cell–matrix and cell–cell adhesions also activate signaling pathways that act coordinately with signals from receptors for growth factors, chemokines, cytokines and morphogens to regulate the cell adhesion, migration, proliferation, survival, and differentiation. In addition to adhesion receptors themselves, large multiprotein complexes are assembled at the cytoplasmic face of these junctions by protein interactions initiated at the intracellular domains of each type of adhesion receptor. Biochemical and cell culture experiments have provided information on how these protein interactions and complexes connect adhesion junctions to the cytoskeleton and the cell's signaling apparatus. Many components of these adhesion complexes have been identified.

Important insights have also been gleaned from gene knockout studies, which have identified critical roles for many components of these adhesion complexes during development. Mutations in protein components of these adhesion complexes have also been identified in the etiology of a variety of human diseases.

1
Cell–matrix Adhesion

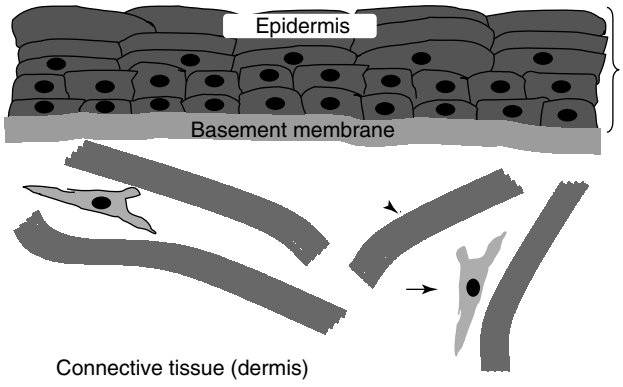
1.1
Overview

The adhesion of cells to extracellular matrix (ECM) proteins is essential for embryonic development, tissue morphogenesis, and homeostasis of all vertebrate organisms. Integrins comprise the major class of cell surface proteins that bind to ECM proteins. Integrins contribute to tissue structure by forming transmembrane links between ECM proteins and the cell's cytoskeleton at sites referred to as cell–matrix junctions. The best-characterized cell–matrix junctions are focal adhesions and hemidesmosomes. At focal adhesions, integrins connect the ECM with the actin microfilament cytoskeleton, and at hemidesmosomes integrins connect the ECM with the intermediate filament cytoskeleton. Integrins are also signaling receptors, providing cells with information to evaluate the composition and physical state of their environment. Integrin signaling contributes to the regulation of cell migration, cell proliferation, survival and differentiation. Important insights into the physiological roles of extracellular matrix proteins and their integrin receptors has been gained from cell culture models, gene knockout approaches in mice, and the analysis of human hereditary disorders involving genes encoding cell adhesion proteins.

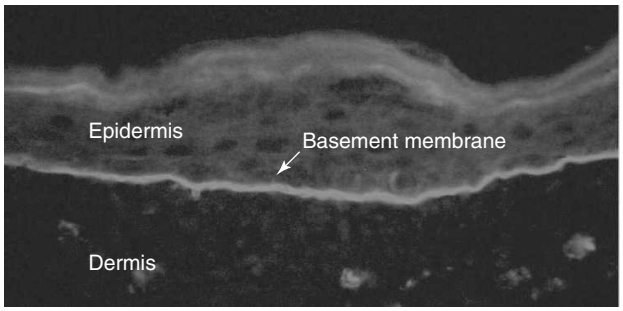
1.2
Extracellular Matrix

The extracellular matrix (ECM) is comprised of cell-secreted macromolecules that form an insoluble meshwork outside cells. The ECM holds cells together in tissues, and tissues together in organs. Large glycoproteins such as collagens, laminins, and fibronectin are important components of the ECM. They contribute to the physical characteristics of the ECM and function as adhesive ligands for cells. Also important to the structure of the ECM are the long, unbranched, charged polysaccharides referred to as glycosaminoglycans (GAGs) and proteins containing GAG chains called proteoglycans. Because of their extended and charged nature, GAGs easily form hydrated gels that are important for tissues to resist compressive forces.

ECM is the major component in connective tissue, such as skin, bone, and cartilage. The ECM is secreted and organized by cells that reside within the connective tissue: fibroblasts in the connective tissue in skin, chondrocytes in cartilage, and osteoblasts in bone. Other cells such as epithelial cells, endothelial cells, and nerve cells secrete ECM proteins that become assembled into a basal lamina or basement membrane (Fig. 1). Unlike the ECM of connective tissue, which surrounds the cells that secrete it, the basement membrane is found only on the basal cell surface of endothelial and epithelial cells. Basement membranes



(a)



(b)

Fig. 1 Extracellular matrices of the skin. (a) A schematic representation of a cross-section of skin. Keratinocytes of the epidermis are shown in red. The basement membrane is shown in green. The connective tissue of the underlying dermis is shown in tan. The black arrows and arrowheads indicate dermal fibroblasts and collagen fibrils respectively. (b) A cross-section of mouse skin stained with fluorescent antibodies that recognize laminin-5. The epidermis consisting of keratinocytes, the basement membrane, and the underlying connective tissue of the dermis are labeled. Bright staining for laminin-5 is seen in the basement membrane. Some background autofluorescence is seen in the upper layers of epidermis. The immunofluorescence micrograph was kindly provided by Dr. Michael DiPersio (see color plate p. xxviii).

separate these cells from connective tissue and other cell types (Fig. 1) and also function as permeability barriers to the passage of macromolecules. This is particularly important in the kidney glomerulus, where the basement membrane regulates the passage of molecules from the blood into the urine. Additionally, the adhesion of cells to basement membranes regulates cell behavior including cell survival, proliferation and differentiation.

1.2.1 **Collagens**

Collagens comprise a large family of related proteins (Table 1) that are important components of all ECMs. All collagens

Tab. 1 Collagens. (Adapted from Prockop, D.J., Kivirikko, K.I. (1995) *Annu. Rev. Biochem.* **64**, 403–434.)

Collagens[a]	***Subunit composition***[b]	***Tissue distribution***
Fibril-forming (fibrillar)		
Type I	$[\alpha_1(I)_2\alpha_2(I)$	Most connective tissues including bone, skin, tendons, ligaments, cornea, internal organs
Type II	$[\alpha_1(II)]_3$	Cartilage, invertebral disc, notochord, vitreous humor of the eye
Type III	$[\alpha_1(III)]_3$	Skin, blood vessels, internal organs
Type V	$[\alpha_1(V)]_2\alpha_2(V)$ and $\alpha_1(V)\alpha_2(V)\alpha_3(V)$	Similar to Type I
Type XI	$\alpha_1(IX)\alpha_2(IX)\alpha_3(IX)$	Similar to Type II
Fibril-associated		
Type IX	$\alpha_1(IX)\alpha_2(IX)\alpha_3(IX)$	Cartilage
Type XII	$[\alpha_1(IV)]2\alpha_2(IV)$	Tendons, ligaments, some other tissues
Network forming		
Type IV	$[\alpha_1(IV)]2\alpha_2(IV)$	Basement membranes
Anchoring filaments		
Type VII	$[\alpha_1(VII)]3$	Beneath stratified squamous epithelia
Transmembrane		
Type XVII (BP180)	$[\alpha_1(XCII)]3$	Hemidesmosomes present in skin

[a] Only a subset of the known collagens are presented.
[b] Collagen subunits are also referred to as collagen chains.

contain a triple helical domain containing three collagen subunits referred to as α-chains or α-subunits. The triple helical structure is dictated by a stretch of glycine-X-Y amino acid repeats in each α-chain, where X and Y are frequently proline and 4-hydroxy-proline respectively. Depending upon the type of collagen, the triple helical domain can form from three identical or different α-chains. Collagens also differ in structure and function. Fibrillar collagens, which are major components of connective tissue, have long stretches of triple helical domains that promote the formation of fibrils and larger fibers. Fibril-associated collagens mediate the interactions of collagen fibrils with each other and with other matrix components. Network-forming collagens form extended lattices that are believed to have important scaffolding functions in basement membranes. The triple helical domains of fibril-associated and network-forming collagens are interrupted with nonhelical domains, making these collagen proteins more flexible. Other collagens form anchoring fibrils that connect basement membranes of stratified epithelia to the underlying connective tissue.

Mutations have been identified in collagen genes that have been linked to human genetic disorders. Mutations in genes that encode type I fibrillar collagen are responsible for the genetic disorder

osteogenesis imperfecta. In its most severe form, this disorder is characterized by brittle bones, abnormal teeth, thin skin, and weak tendons, which reflects the wide tissue distribution of type I collagen. Mutations in genes that encode type II collagen, which is found mostly in cartilage, are responsible for disorders referred to as chondrodysplasias. Affected individuals can have bone and joint deformities. Mutations in genes that encode type III collagen affect the integrity of blood vessels and skin, reflecting the tissue distribution of type III collagen. Null mutations in the homologous genes in mice result in similar phenotypes.

1.2.2 **Laminins**

Laminins comprise a family of high molecular weight heterotrimers that are essential components of basement membranes (Table 2). Each laminin contains one α-subunit, one β-subunit, and one γ-subunit. To date there are five known α-subunits, three known β-subunits, and three known γ-subunits that form 12 different laminin isoforms, each containing a distinct combination of α-, β- and γ-subunits that assemble in a cross-like structure with one coil-coiled domain containing portions of all three subunits. Most information about the tissue distribution of individual laminin subunits is known (Table 3). However, the expression and function of laminin isoforms in specific tissues has also been established. For example, laminin-1 ($\alpha_1\beta_1\gamma_1$) expression is critical for early vertebrate development. Laminin-2 ($\alpha_2\beta_1\gamma_1$) and laminin-4 ($\alpha_2\beta_2\gamma_1$) play important roles in the development and maintenance of muscles and nerves. Mutations in the gene for the laminin α_2 subunit, which is present in both laminin-2 and laminin-4, cause some forms of congenital muscular dystrophy in humans, in which affected individuals show both muscular and neurological defects. Laminin-5 ($\alpha_3\beta_3\gamma_2$) is present in basement membranes of stratified epithelia. Epithelial cell adhesion to laminin-5 is required for epithelial tissues to resist physical stress. Laminin-5 is also discussed in Sect. 1.5, because of its central role in cell–matrix junctions known as hemidesmosomes. Laminins also play a critical role in the kidney where laminin expression is differentially regulated for kidney development and function. Laminin-1 ($\alpha_1\beta_1\gamma_1$), laminin-8 ($\alpha_4\beta_1\gamma_1$) and laminin-10 ($\alpha_5\beta_1\gamma_1$) are expressed early in the formation of the glomerular basement membrane. These laminins are later replaced by laminin-9 ($\alpha_4\beta_2\gamma_1$) and finally by laminin-11 ($\alpha_5\beta_2\gamma_1$). Mice with null mutations in the gene encoding the laminin α_5 subunit lack one or both kidneys. When one kidney is present in α_5 laminin-null mice, this kidney is smaller than normal and shows defects in glomerulogenesis and in the glomerular basement membrane. As indicated above, the basement membrane of kidney glomeruli performs an important filtration function, and β_2

Tab. 2 Laminins.

Laminins	*Chain composition*
Laminin 1	$\alpha_1\beta_1\gamma_1$
Laminin 2	$\alpha_2\beta_1\gamma_1$

Tab. 3 Tissue distribution of laminin chains. (Adapted from Patarroyo et al. (2002) *Seminars in Cancer Biol.*, **12**, 197–207).

Laminin chain	*Tissue distribution*
α_1	Early embryo, neuroretina, kidney proximal tubes, salivary, and mammary glands
α_2	Skeletal and cardiac muscle, peripheral nerve, a few capillaries, trophoblast, brain, and other tissues
α_3	Skin and most other epithelia
α_4	Fetal skeletal muscle, cardiac and visceral smooth muscle, nerve, blood vessel endothelia, bone marrow, and other tissues
α_5	Diverse epithelia, kidney, blood vessels, bone marrow, developing muscle and nerve, synaptic BM
β_1	Most tissues
β_2	Neuromuscular junction, blood vessels, kidney glomerulus
β_3	Skin and most other epithelia
γ_1	Most tissues
γ_2	Skin and most other epithelia
γ_3	Kidney, lung, reproductive tract, nerve, and brain

subunit containing laminins play a critical role in this filtration function. Mice with a null mutation in the laminin β_2 gene maintain high levels of expression of the β_1 laminin chain; nonetheless, these mice die after birth because of massive proteinuria, because of the failure of the glomerular basement membrane to function as a filtration barrier. Thus, laminins play isoform-specific roles in tissue differentiation and function.

1.2.3 Other Extracellular Matrix Proteins

In addition to collagens and laminins, there are other ECM proteins that play important roles in regulating cell behavior, including fibronectin and fibrinogen/fibrin. Fibronectin is a large disulfide-linked dimer that is present in a soluble form in blood. Fibronectin is also secreted by fibroblasts and other cells into the ECM where it forms fibrils associated with the cell surface. Like laminin-1, fibronectin is essential for early vertebrate development. Characterization of fibronectin-null embryos indicated a requirement for fibronectin in the development of mesodermal structures, blood vessels, and the heart. Fibronectin also plays an important role in wound healing in the adult. During cutaneous wound healing, a provisional matrix is formed from plasma proteins released from injured vessels. These proteins include fibronectin and fibrinogen. Fibrinogen is proteolytically processed at the site of blood vessel injury to form a fibrin clot. This provisional matrix supports the formation of new blood vessels, the proliferation of fibroblasts and the reepithelialization of the wound. The provisional matrix is eventually replaced by the normal ECM of the skin.

In summary, extracellular matrices are essential to tissue and organ structure and development not only because of their scaffolding function but also because they provide important regulatory information that guides cell behavior and differentiation. As discussed in the next sections, much of this information is relayed by integrin receptors that

provide the physical link at cell–matrix junctions.

1.3 Integrins

1.3.1 The Integrin Family

Integrins comprise a large family of cell surface proteins. They are heterodimeric transmembrane receptors for ECM proteins (Fig. 2). Each integrin contains one α-subunit and one β-subunit. Both α- and β-subunits pass through the plasma membrane, and each subunit contains a relatively large extracellular segment with a globular ligand-binding domain. Most α- and β-subunits also contain relatively small intracellular domains (cytoplasmic domains or tails) consisting of from 13 to 70 amino acids. The exception is the β_4 subunit cytoplasmic domain, which contains 1000 amino acids.

Integrins are highly evolutionarily conserved. Integrin homologs have been identified in all metazoans from flies and nematodes to humans. In mammals, there are currently 8 known β-subunits and 18 α-subunits that heterodimerize in different combinations to generate 24 distinct integrin heterodimers (Table 4). Several integrin subunits can be modified by alternative splicing, further adding to the complexity of the integrin family. The specific combination of α- and β-subunits determines ligand-binding specificity. Some integrins are specific for a single component of the ECM, such as the $\alpha_5\beta_1$ integrin that binds only to fibronectin. Most integrin heterodimers can bind to more than one extracellular matrix component. The $\alpha_v\beta_3$ integrin is one of the more promiscuous integrins; it binds to vitronectin, fibronectin, and fibrinogen, among other ECM components.

Most cells express several different integrin heterodimers allowing them to interact with multiple components of the ECM, and a cell's integrin repertoire can be regulated both developmentally and in response to changes in the physiological environment. Although most integrin heterodimers are expressed by a variety of cell types, some integrins are expressed in a cell-type specific manner. The $\alpha_{IIb}\beta_3$ integrin is expressed only in platelets. The $\alpha_7\beta_1$ integrin is expressed exclusively in neuronal cells and integrins containing the β_2 subunit are expressed only by immune cells also referred to as leukocytes.

The identification of human hereditary diseases involving mutations in genes encoding integrins, and the analysis of null mutations in integrin genes in mice have underscored the importance of integrin receptors in physiological and developmental processes. To date there are four inherited disorders involving integrins. Leukocyte adhesion deficiency-1 (LAD1) is caused by mutations in the integrin β_2 subunit where affected individuals show

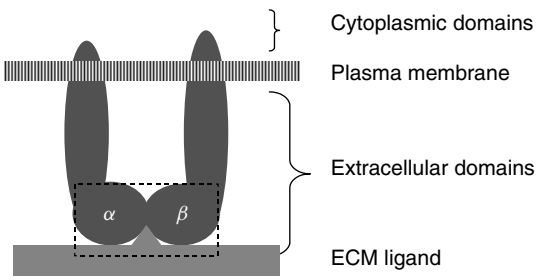

Fig. 2 Integrin heterodimer. Shown is a schematic representation of an integrin heterodimer. The typical small cytoplasmic domains and large extracellular domains of the α- and β-subunits are indicated by brackets. The N-terminal globular domains of the α- and β-subunits that function in ligand binding are indicated by a dashed box.

Integrin	*Ligand[a] (ECM, soluble, counter receptors)*
$\alpha_1\beta_1$	Co, Ln[2]
$\alpha_2\beta_1$	Co, Ln
$\alpha_3\beta_1$	Ln
$\alpha_4\beta_1$	Fn, VCAM
$\alpha_4\beta_7$	Fn, VCAM, MadCAM
$\alpha_5\beta_1$	Fn
$\alpha_6\beta_1$	Ln
$\alpha_6\beta_4$	Ln
$\alpha_7\beta_1$	Ln
$\alpha_8\beta_1$	Fn, Tn, VCAM
$\alpha_9\beta_1$	Tn, Co, Ln, VCAM
$\alpha_{10}\beta_1$	Co
$\alpha_{11}\beta_1$	Co
$\alpha_v\beta_1$	Fn, Vn
$\alpha_v\beta_3$	Vn, Fn, vWF, Op, Tn
$\alpha_v\beta_5$	Vn
$\alpha_v\beta_6$	Fn, Tn
$\alpha_v\beta_8$	Co, Ln, Fn
$\alpha_{IIb}\beta_3$	Vn, Fn, vWF, Fg, Fg
$\alpha_L\beta_2$	ICAM 1–5
$\alpha_M\beta_2$	Fg, iC3b, ICAM
$\alpha_x\beta_2$	Fg, iC3b
$\alpha_D\beta_2$	ICAM, VAM
$\alpha_E\beta_7$	E-cadherin

[a] ECM, soluble, and counter receptors ligands are shown in red, blue, and green, respectively.

severe deficiencies in their immune responses. Glanzmann's thrombasthenia, a bleeding disorder, is caused by mutations that prevent the proper expression of the $\alpha_{IIb}\beta_3$ platelet integrin and some mild forms of muscular dystrophy are associated with mutations in the α_7 subunit, which affect the function of the $\alpha_7\beta_1$ laminin binding integrin. Additionally, mutations that inhibit $\alpha_6\beta_4$ function result in a skin blistering disorder (see Sect. 1.5). These phenotypes are recapitulated in mice carrying the corresponding homozygous null mutations in genes encoding the β_2, α_{IIb}, β_3, α_7, α_6, and β_4 integrin subunits.

The generation of targeted deletions in integrin genes in mice has probably provided the most insight into the developmental role of individual integrin heterodimers. Homozygous null mutations in the gene encoding the integrin β_1 subunit gene result in early embryonic lethality with defects in implantation and gastrulation. Targeted deletion of the integrins α_5 and α_4 subunit genes also result in embryonic lethality. The α_5-null embryos have defects in vascular and mesoderm development, whereas α_4-null embryos show defects in heart development. Deletion of the integrin α_8 subunit gene results in defects in kidney development and deletion of the integrin α_9 subunit results in defects in the development of the lymphatics and thoracic duct. The α_9-null mice die several days after birth from respiratory failure due to fluid accumulation. Mice with null mutations in the integrin α_3 subunit gene show abnormalities in kidney and lung development and also have a skin blistering phenotype. Interestingly, null mutations in some integrin genes do not produce obvious developmental phenotypes. However, in some instances, phenotypes are observed in adult animals when challenged or stressed in some way. For example, mice with null mutations in the integrin β_6 subunit gene are viable and fertile but show increased skin and lung inflammation in response to environmental triggers.

1.3.2 Integrin Ligands

In addition to ECM ligands, some integrins have soluble ligands, and other integrins bind to cell surface receptors (counterreceptors) on neighboring cells

(Table 4). For example, the platelet integrin $\alpha_{IIb}\beta_3$ binds to soluble fibrinogen leading to platelet aggregation. β_2 integrins bind to counterreceptors on the surface of other cells. For example, the $\alpha_L\beta_2$ integrin expressed on T-lymphocytes binds to its counterreceptor ICAM-1 expressed on antigen-presenting cells, leading to the formation of the adhesion complex known as the *immune synapse*, which is required for full and sustained T-lymphocyte activation. The $\alpha_L\beta_2$ integrin is also expressed on neutrophils and monocytes/macrophages and can bind to ICAM-1 expressed on the endothelial cells that line blood vessels. Similarly, the $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins expressed on leukocytes can bind to their counterreceptor(s), VCAM-1 and MadCAM-1 ($\alpha_4\beta_7$ only) on endothelial cells. The binding of leukocyte integrins to their counterreceptors on endothelial cells is important to enable leukocytes to exit the circulation in order to fight infection in tissues in the case of neutrophils and monocyte/macrophages, or to enter lymphoid tissues in the case of T-lymphocytes.

1.3.3 Integrin Signaling

The most intriguing aspect of integrin biology is the ability of integrins to function as bidirectional signaling receptors. Ligand binding to integrins induces transmembrane conformational changes that transduce signals to integrin intracellular domains, resulting in the linkage of integrins to cytoskeletal networks and signaling pathways that regulate cell behavior. The process by which ligand binding to integrins activates intracellular signals is referred to as integrin ''outside-in'' signaling.

Integrin ''outside-in'' signaling provides cells with important information about their ECM environment that allows them to make decisions regarding proliferation, survival, migration, and differentiation in response to growth factors, cytokines, chemokines, and morphogens. The formation of integrin-ECM adhesions regulates these processes by activating cascades of biochemical signals that regulate the assembly of cytoskeletal networks and signaling complexes (Fig. 3). The formation of signaling complexes is regulated by protein–protein interactions. For example, Src homology 2 (SH2) domains bind to phosphorylated tyrosine residues in proteins. Thus, the activation of tyrosine kinase signaling generates binding sites for SH2 domains, providing a mechanism to recruit proteins to signaling complexes. Other protein interactions are mediated by Src homology 3 (SH3) domains; these domains bind to proline-rich regions in other proteins. There are still other conserved domains that mediate protein–protein interactions; these will be described as they become relevant to the discussion.

An early signaling event that follows integrin engagement in cell adhesion is the activation of the cytoplasmic tyrosine kinase, focal adhesion kinase (FAK). Integrins trigger the autophosphorylation of FAK at tyrosine 397, which promotes the association of Src family of cytoplasmic tyrosine kinases and other signaling proteins such as phosphoinositide (PI) 3-kinase and phospholipase Cγ via their SH2 domains. Src kinases phosphorylate FAK's kinase domain and also tyrosine 925, increasing FAK's kinase activity and promoting the binding of SH2 domain containing signaling proteins at tyrosine 925, including Grb2, and Grb7. Activated FAK/Src kinase complexes trigger a cascade of protein tyrosine phosphorylations, including the phosphorylation of the adaptor proteins paxillin and p130Cas, which in turn promotes the formation of protein complexes

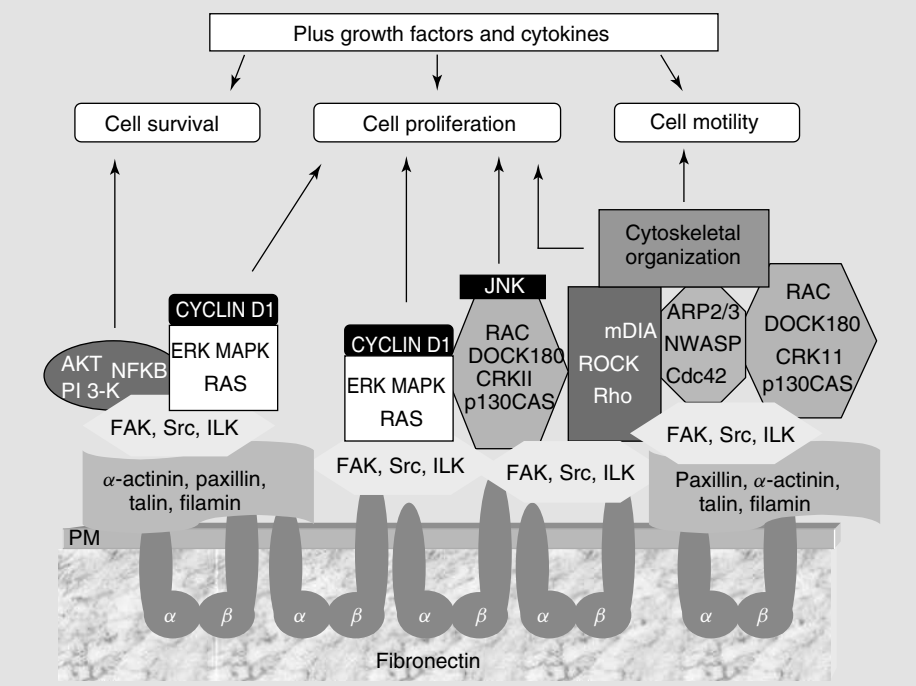

Fig. 3 Integrin signaling. Pathways regulated by integrin signaling that promote cell motility, proliferation, and survival are shown in the diagram. Integrins signal together with growth factor and cytokine receptors to regulate cell motility, survival, and proliferation, although the mechanisms of cooperation between these different types of cell surface receptors are not fully defined. Most of the cytoskeletal, adaptor and signaling proteins are described in the text. In addition to these are the NFKB transcription factor, the kinase ROCK, which is activated by Rho and in turn activates actinomyosin contractility, and mDIA, which is also activated by Rho to promote actin polymerization. Also shown is Cdc42, which activates NWASP, which in turn activates the Arp2/3 complex to nucleate actin polymerization.

that trigger many downstream signals. The small GTP-binding protein Ras gets activated downstream of FAK/Src kinases and, in turn, Ras triggers the activation of ERK MAP kinase and PI 3-kinase. However, FAK can also activate PI 3-kinase directly. In turn, PI 3-kinase plays a role in the activation of several other signaling proteins. It generates PIP3 phospholipids, which provide bindings sites at the plasma membrane for PH domains, which are conserved domains present on many different types of signaling proteins. PI 3-kinase signaling plays a role in activating the kinase AKT and the Rho family of GTP-binding proteins, Cdc42, Rac and Rho. AKT signaling promotes cell survival and proliferation, whereas the Rho family GTPases regulate the actin cytoskeleton. The Rho family is particularly important in adhesion signaling. Cdc42 and Rac promote actin polymerization, resulting in the formation of filopodia and lamellipodia, respectively. The formation of these structures drives cell spreading and migration. Rho promotes the formation of

stress fibers and focal adhesions to regulate cell–matrix adhesion and contractility.

FAK and paxillin are important regulators of cell spreading and cell migration. FAK/Src complexes trigger the phosphorylation of p130Cas. Phosphorylated p130Cas recruits additional signaling proteins including the adaptor protein CrkII, and Dock180, which is a guanine exchange factor (GEF) that activates Rac. Integrin-mediated adhesion is sufficient to activate Rac, and is also required for the membrane targeting of activated Rac and its association with downstream effectors. Thus, even when Rac is activated by signals from other cell surface receptors, such as growth factor receptors, integrin-mediated adhesion is still required for Rac to activate downstream signaling pathways. Activated FAK/Src complexes also trigger the tyrosine phosphorylation of paxillin, which can also lead to the recruitment of CrkII and potential activation of Rac by similar pathways. However, current evidence suggests that paxillin regulates migration by binding of paxillin-kinase linker (PKL). PKL is an Arf GTPase activating protein (GAP) that regulates vesicular trafficking. In addition, PKL binds to the Cdc42/Rac GEF, PAK interacting exchange factor (PIX), another GEF for Rac. PKL also binds to the serine/threonine kinase PAK, which is activated by Rac to promote cell migration. Thus, paxillin-PKL association may provide the appropriately localized scaffold for the activation of signaling complexes that are required to direct cell migration.

In addition, stable integrin-mediated adhesion cooperates with other cell surface receptors such as growth factor receptors to regulate cell behavior, such as proliferation, survival, and differentiation. Numerous studies have demonstrated an important role for integrins in the regulation of cell proliferation. Most normal cells require integrin-mediated adhesion to specific components of the ECM for cell proliferation; activation of growth factor receptors is not sufficient. Integrins promote cell proliferation by regulating the activities of the G1 cyclin-dependent kinases (Cdk4/6 and Cdk2). Integrin-mediated adhesion is necessary for the transcription of cyclin D1, which is required for the activation of the cyclin-dependent kinase(s) Cdk4/6. The cyclin D1 promoter is regulated by transcription factors that are phosphorylated and activated by ERK. Integrin-mediated adhesion is required for integrin- and growth factor-activated ERK to be translocated to the nucleus and for the sustained ERK activity that is necessary to induce transcription from the cyclin D1 promoter. Integrin signaling is also required for the activation of cyclin E-Cdk2. Integrin-mediated adhesion promotes cyclin E-Cdk2 activity by contributing to the downregulation of the Cdk inhibitors, p21 and p27.

In some cell types, the ability of cell–matrix adhesion to promote cell proliferation is dependent upon the integrin heterodimer mediating adhesion. The $\alpha_5\beta_1$-mediated endothelial cell adhesion to fibronectin promotes proliferation in response to growth factors, whereas $\alpha_2\beta_1$-mediated endothelial adhesion to laminin1 does not. Interestingly, this regulation is at the level of cyclin D1 translation and depends on Rac signaling, which occurs efficiently when cells are adhered to fibronectin, but not to laminin1. Thus, integrin signaling not only promotes the transcription of cyclin D1, but can also regulate the translation of cyclin D1 by modulating the activation of Rac signaling.

''Inside-out'' integrin signaling provides cells with a mechanism to rapidly regulate integrin function. In some cell types, the ability of integrins to bind

their ligands is tightly regulated. In these cells, intracellular signals trigger conformational changes in integrins that regulate the ability of their extracellular domains to bind to their ligands. This is referred to as integrin "inside-out" signaling and is most prevalent in circulating blood cells, including platelets and leukocytes, such as neutrophils, monocytes and T-lymphocytes. The best-studied examples of inside-out signaling are the regulation of $\alpha_{IIb}\beta_3$ integrin on platelets and β_2 integrins and leukocytes. As mentioned above, the $\alpha_{IIb}\beta_3$ integrin promotes platelet aggregation by binding to soluble fibrinogen. Although platelet aggregation is important in preventing excessive bleeding when blood vessels are injured, inappropriate platelet aggregation can lead to thrombosis. Thus, the $\alpha_{IIb}\beta_3$ integrin is inactive on resting platelets, and when platelets become activated at sites of blood vessel injury, intracellular signaling events activate $\alpha_{IIb}\beta_3$. The $\alpha_{IIb}\beta_3$ integrin is then able to bind to soluble fibrinogen with high affinity and promote the formation of platelet aggregates or plugs to stop bleeding.

Similarly, the activity of β_2 integrins (Table 4) is also tightly regulated to prevent the inappropriate activation of an immune response. The activation of β_2 integrins involves conformational changes that increase the affinity of ligand binding; however, changes in the avidity with which β_2 integrins interact with their ligands is also important. Signals that increase the avidity of β_2 integrin-ligand interactions promote the diffusion and clustering of β_2 integrins on the cell surface. In the case of inactivated T-lymphocytes, β_2 integrins are tethered to the actin cytoskeleton in an inactive state. Signals that activate T-lymphocytes release β_2 integrins from the cytoskeleton. β_2 integrins are then free to diffuse on the plasma membrane, cluster and form new attachments to the cytoskeleton at adhesion sites.

Both inside-out and outside-in integrin signaling are mediated by conformational changes in the integrin heterodimer. Interestingly, the characterization of conformation-dependent antibodies to integrins has indicated that the conformations of activated and ligand-bound integrins are similar. Recent electron microscopy, X-ray crystallography, NMR, and mutational studies have provided important insight into the conformational regulation of integrin activity. These studies suggest that integrins in the low affinity state (inactive) have a bent, closed conformation with their globular ligand binding heads bent toward the plasma membrane and their α- and β-subunits closely associated (Fig. 4). In contrast, integrins in the high affinity state (fully active) have straightened and opened conformations with their α- and β-subunits separated and their globular domains extended away from the plasma membrane for ligand binding (Fig. 4). Integrins in the intermediate affinity state have their ligand-binding domains extended from the plasma membrane; however, their conformations are not fully opened. Current evidence suggests that these integrin conformations are in dynamic equilibrium and that conditions that inactivate or activate integrins shift this equilibrium.

1.3.4 Integrin-associated Proteins

The ability of integrins to mediate adhesion and to activate signals depends on their interaction with other cellular proteins (Table 5). Most integrins associate with the cytoskeleton and signaling complexes by protein interactions mediated by their β-subunit cytoplasmic domain (β-tail). In fact, clustering isolated β_1 and β_3

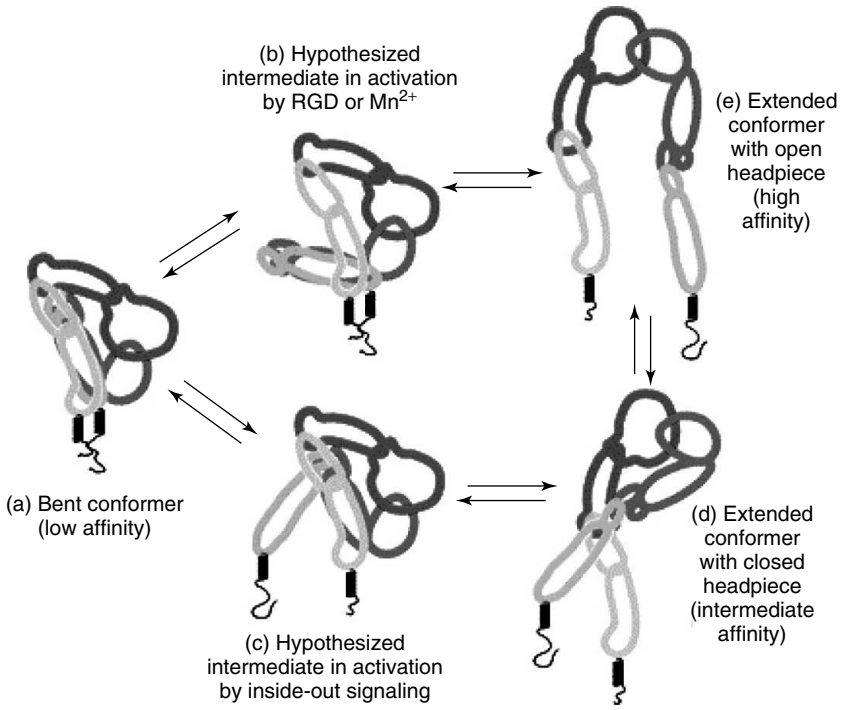

Fig. 4 Conformational changes in integrin structure associated with integrin activation. Results from X-Ray crystallography, electron microscopy and mutational studies suggest that integrins with different ligand-binding affinities have different conformations. Integrins with a bent structure are in the low affinity conformation (a), whereas Sho integrins with an extended structure with an open headpiece (consisting of the globular ligand-binding domains) are in the high affinity conformation (e). Integrins in intermediate affinity conformations have extended structures, but with closed headpieces (d). Other intermediate affinity conformations have been hypothesized (b and c). (Reprinted with permission from Takagi, J., Petre, B.M., Walz, T., Springer, T.A. (2002) Global conformational rearrangements in integrin extracellular domains in outside-in and inside-out signaling, *Cell* **110**, 599–611).

tails is sufficient to activate tyrosine kinase and Rac signaling.

The eight integrin β-tails have varying degrees of amino acid homology (Fig. 5) with the β_1, β_2, and β_3 tails showing the most similarity. Not surprisingly, several proteins have been shown to bind to more than one of these β-tails, whereas other protein interactions are β-tail specific. The β_8 tail has no homology with other integrin β-tails and to date no proteins have been identified that bind to the β_8 tail. The β_4 tail shows no similarity with other β tails except that it contains NPXY and NXXY motifs that are present in other β-tails. Protein interactions with the β_4 tail will be discussed in Sect. 1.5.

The β_1, β_2 and β_3 cytoplasmic tails share considerable amino acid sequence homology and the cytoskeletal linker protein talin has been shown to bind to all three tails. Since talin binds to actin and the actin binding protein vinculin, integrin-talin interactions are likely to regulate many

Tab. 5 Integrin binding proteins.

Integrin binding proteins	*β-tail*	*α-tail*	*Other regions*
Talin	$\beta_1, \beta_2, \beta_3$		
Filamin	$\beta_1, \beta_2, \beta_3, \beta_7$		
α-actinin	β_1, β_2

Nischarin		α_5	
CD47(1AP) (tetraspanins)			$\alpha_v\beta_3, \alpha_{\text{IIb}}\beta_3, \alpha_2\beta_1$
CD9 (tetraspanins)			Multiple integrins
CD81 (tetraspanins)			$\alpha_3\beta_1, \alpha_6\beta_1$
CD151 (tetraspanins)			$\alpha_3\beta_1, \alpha_6\beta_1, \alpha_6\beta_4, \alpha_7\beta_1$
Caveolin			$\alpha_1\beta_1, \alpha_5\beta_1, \alpha_v\beta_3$

[a] Paxillin has been shown to bind to both α- and β-tails.

processes requiring integrin-cytoskeletal interactions. Talin also binds to FAK, linking integrins to several signaling pathways (see Sect. 1.3.3). The cytoskeletal proteins, filamin and α-actinin, provide additional linkages between integrins and the actin cytoskeleton. The actin binding protein α-actinin can bind to the β_1 and β_2 tails, whereas filamin binds to the β_1, β_2, and β_7 tails. Filamin also links integrins to signaling pathways that regulate the actin cytoskeleton, including RalA, Rho family GTPases, their activators, as well as PAK. Thus, filamin–integrin interactions may be important in directing the actin assembly to sites of integrin-mediated adhesion. Skelemin has recently been shown to bind to the β_1 and β_3 cytoplasmic tails, and current evidence suggests that it may function in regulating integrin-mediated cell spreading. Skelemin is a muscle-specific protein that binds to myosin; however, evidence is accumulating suggesting that a skelemin-related protein is expressed in nonmuscle cells, suggesting that skelemin-β tail interactions may regulate integrin function in several cell types.

Integrin-β cytoplasmic domains have also been shown to bind to signaling proteins. The membrane-proximal regions of the β_1, β_2, and β_3 cytoplasmic domains bind to FAK, and the same region of the β_1 and β_3 tails can also bind to paxillin. The functional significance of these interactions is not yet known; however, mutations in the FAK binding region in the β-tail do not inhibit the activation

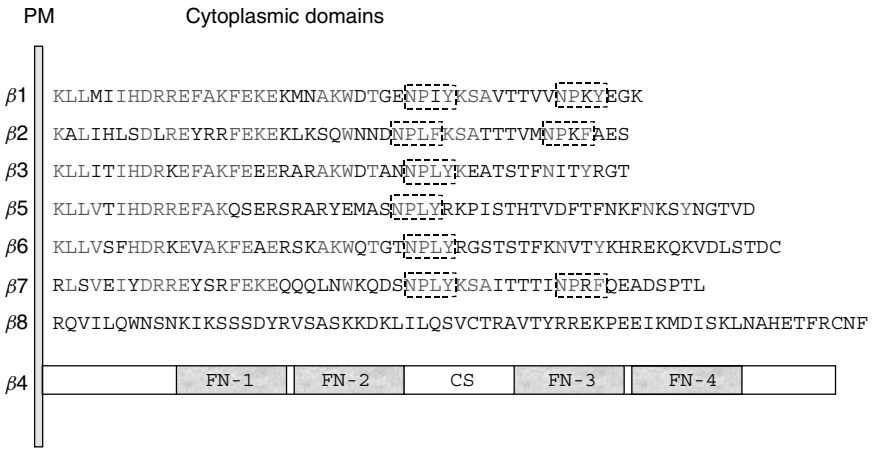

Fig. 5 Comparison of integrin β-subunit cytoplasmic domains. The amino acid sequences of the $\beta_1-\beta_8$ cytoplasmic domains are shown, with the exception of β_4. Amino acids that are conserved in at least three β-cytoplasmic domains are shown in red. The β_2 and β_7 cytoplasmic domains contain NPXF motifs in place of NPXY motifs found in other β-cytoplasmic domains. These phenylalanine residues (F) are shown in green. The conserved NPXY/F motifs are indicated by dashed boxes. The β_4 cytoplasmic domain contains 1000 amino acids with 4 regions homologous to conserved domains identified first in fibronectin, referred to as fibronectin type III repeats. These regions are labeled FN-1 to FN-4 in the β_4 cytoplasmic domain. The first pair of FN repeats is separated by a region referred to as the connecting segment (CS) (see color plate p. xxiii).

of FAK by integrins. Interestingly, phosphorylated FAK has been shown to bind to the C-terminal region of the β_5 tail. This interaction is important for vascular endothelial growth factor (VEGF) to promote migration mediated by the $\alpha_v\beta_5$ integrin. Integrin-linked kinase (ILK) has also been shown to bind to the β_1 and β_3 tails. In addition to its serine/threonine kinase activity, ILK also functions as an adaptor protein that localizes to focal adhesions. ILK plays a role in the regulation of cell adhesion, cell proliferation and fibronectin matrix assembly; however, there is no evidence that ILK-β tail interactions are required for ILK function in these processes.

β tail–specific protein interactions have been identified for the β_1, β_2, β_3, and β_5 cytoplasmic domains. Many of these interactions regulate integrin-ligand interactions. Cytohesins bind specifically to the β_2 cytoplasmic domain to upregulate β_2 integrin-dependent adhesion. β_3-endonexin binds specifically to the β_3 tail and increases the ability of $\alpha_{IIb}\beta_3$ to bind to its ligand. Although talin is not a β-tail-specific binding protein, it is interesting to note that the binding of a fragment of talin to the β_3 tail can also activate $\alpha_{IIb}\beta_3$. Thus, β_3-endonexin and talin may both regulate the activation of $\alpha_{IIb}\beta_3$. TAP-20 binds specifically to the β_5 tail and appears to play a role in promoting $\alpha_v\beta_5$-dependent migration by decreasing $\alpha_v\beta_5$-mediated adhesion. Interestingly, TAP-20 shares amino acid homology with β_3-endonexin, although their functions may be distinct since β_3-endonexin enhances $\alpha_{IIb}\beta_3$-ligand interactions. Integrin-associated protein-1 (ICAP-1) binds specifically to the β_1 cytoplasmic

domain; there is some evidence that this interaction promotes cell migration.

Recently, phosphotyrosine-binding (PTB) domains have been shown to be involved in some protein interactions with integrin β-tails. The PTB domain represents another conserved protein–protein interaction domain. PTB domains bind to NPXY and NPXF motifs found in many proteins, including most integrin β-tails. Recent studies have indicated that the region of talin that binds to integrins has a three-dimensional structure similar to a PTB domain. Talin's PTB domain has been shown to bind to the membrane-proximal NPXY motif in the integrin β-tail. Interestingly, this β-tail motif is required for most aspects of integrin function. Some PTB domains bind NPXY motifs when the tyrosine residue is phosphorylated. However, talin-integrin β-tail interactions do not require tyrosine phosphorylation. ICAP-1 also interacts with the integrin β_1 cytoplasmic domain via a PTP domain, but requires the C-terminal NPXY motif of the β_1 tail. Recently, PTB domains from several other proteins have been shown to bind to integrin β-tails, although the functional significance of these interactions is not yet known. Nonetheless, since NPXY/F motifs are highly conserved among the different β-tails, as well as across species, it is likely that β-tail–PTB domain interactions will play central roles in integrin function. The binding of some PTP domain-containing proteins to individual β-tails may require the tyrosine phosphorylation of the NPXY, motifs further increasing the diversity of protein interactions with β-tails and the mechanisms that regulate them.

Several proteins have been identified that bind to α-subunit cytoplasmic domains (Table 5). The functional significance of the interaction of paxillin with the α_4 tail has been established. This association modulates cell migration mediated by integrins containing α_4 tails. Additionally, serine phosphorylation of α_4 tails has been shown to inhibit the binding of paxillin. Thus, paxillin-α_4 tail association and α_4 integrin-dependent cell migration are likely to be regulated by signaling pathways that modulate the phosphorylation of the α_4 tail. Paxillin has also been shown to bind to the α_9 tail to regulate $\alpha_9\beta_1$-dependent cell migration. The ability of paxillin to regulate migration by this mechanism is likely to be important for $\alpha_4\beta_1$, $\alpha_4\beta_7$, and $\alpha_9\beta_1$ function during development and $\alpha_4\beta_1$ and $\alpha_4\beta_7$ function during the immune response.

Integrins also associate with other transmembrane proteins, including caveolin, tetraspanins (TM4 proteins) and CD47 (also known as integrin-associated protein, IAP). Caveolin binds to the α-subunit of several integrin heterodimers, including $\alpha_5\beta_1$ and links these integrins to Fyn, an Src family kinase that can couple integrins to the Ras/ERK MAP kinase pathway, which is important for cell proliferation. Several members of the TM4 family have been shown to bind to integrin α-subunit extracellular domains. The strongest association appears to be between CD151 and $\alpha_3\beta_1$. The cytoplasmic domain of CD151 recruits the signaling proteins phosphatidylinositol 4-kinase and protein kinase C to CD151-integrin complexes. These signaling proteins regulate the actin cytoskeleton and cell spreading. Interestingly, mutations that inhibit the association of CD151 and $\alpha_3\beta_1$ also inhibit cell spreading, indicating that this association is functionally significant. CD47 is also an important regulator of integrin function. CD47 associates with β_1, β_2,

and β_3 integrins in cholesterol-rich membrane domains. CD47-integrin association enhances the interaction of integrins with their ligands, as well as integrin function in adhesion and migration. The mechanisms involve signaling through heterotrimeric Giα proteins.

1.4 Focal Adhesions

1.4.1 Components of Focal Adhesion

One of the most studied cell–matrix junctions is the focal adhesion, sometimes referred to as the focal contact. Focal adhesions contain clustered integrins that mediate very tight adhesion with their ECM ligands and also associate with the ends of actin stress fibers. More than 50 proteins have been shown to localize to focal adhesions. Not surprisingly, many of the proteins that can bind to integrin-β cytoplasmic domains, as well as proteins that function in integrin signaling pathways are concentrated in focal adhesions (Figs. 3 and 6). As discussed above, several of these proteins are tyrosine-phosphorylated; thus, focal adhesions can be visualized by using antibodies that recognize phosphotyrosine residues (Fig. 7). In general, focal adhesion proteins contain multiple protein–protein interaction domains enabling them to bind to several proteins simultaneously. Indeed, many focal adhesion proteins function in multiprotein complexes linking integrins, the actin cytoskeleton and multiple signaling cascades. For example, FAK binds to paxillin, talin, p130Cas, Src family kinases, PI 3-kinase, Grb2, and Grb7. Paxillin binding partners include vinculin, FAK, ILK, the tyrosine phosphatase PTP-PEST, PKL, and CrkII. Long lists of binding partners can be made for most focal adhesion proteins. On the basis of biochemical studies that have characterized protein–protein

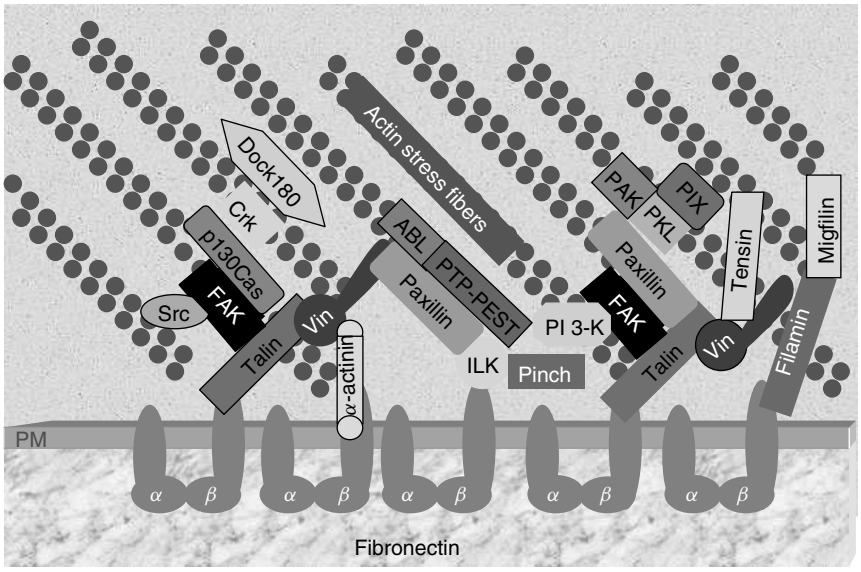

Fig. 6 Components of focal adhesions. Shown is a schematic of a focal adhesion. Only a subset of proteins and protein interactions present at focal adhesion is shown. Vinculin is abbreviated as vin.

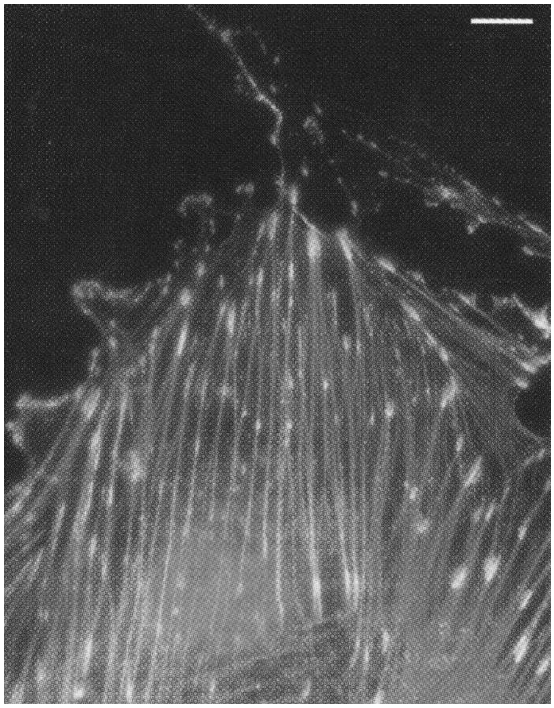

Fig. 7 Tyrosine phosphorylated proteins at focal adhesions. Shown is a rat embryo fibroblast stained for actin in stress fibers (green) and with antibodies that recognize phosphotyrosine (red). Phosphotyrosine staining is seen in focal adhesions at the ends of stress fibers. Regions of overlapping red and green staining are yellow. (Reprinted with permission from Burridge, K., Chrzanowska-Wodnicka, M., Zong, C. (1997) Focal adhesion assembly, *Trends Cell Biol.* **7**, 342–347.) (see color plate p. xxvii).

interactions involving integrins and other focal adhesion proteins, complex linkage maps have been proposed connecting integrins to the activation of various signaling pathways (Figs. 3 and 6). Surprisingly, new focal adhesion proteins are still being identified every year. The most recently identified focal adhesion protein is the Migfilin, which is a filamin-binding protein that regulates cell spreading.

1.4.2 **Regulation of Focal Adhesion Assembly**

Focal adhesions are formed by most cell types when cultured on two-dimensional substrates. The assembly of focal adhesions has been studied in spreading and migrating cells. In these instances, the activation of Rac or Cdc42, either by integrin or growth factor signaling, promotes the formation of filopodia and lamellipodia and new integrin-mediated cell–matrix junctions. These nascent adhesions, referred to as focal complexes, contain integrins, as well as a subset of focal adhesions proteins. Following the activation of Rho and actinomyosin contractility, focal complexes mature into focal adhesions with their associated stress fibers. The formation of focal adhesion has also been studied in quiescent cells, where the activation Rho and downstream myosin II-dependent contractility by extracellular factors induces focal adhesion formation. Focal adhesion formation can also be promoted when external force is applied to integrin-mediated adhesions. When this force is increased, focal adhesions become larger, whereas a reduction in the applied force causes disassembly of focal adhesions. The stimulation of focal adhesion formation by external force also requires Rho signaling,

but appears to be independent of myosin II. Importantly, the stimulation of focal adhesion formation by external forces leads to activation of integrin signaling with physiological consequences. For example, increases in blood flow result in enhanced hemodynamic shear stress placed on integrin-mediated adhesions on the basal surface of endothelial cells, resulting in the remodeling of adhesion sites and the activation of integrin signaling. The increased integrin signaling and subsequent changes in gene expression are thought to play an important role in the development of atherosclerotic plaques. Thus, integrin-mediated adhesions are important sites at which cells sense and respond to changes in their physical environment, a process referred to as mechanotransduction.

1.5 Hemidesmosomes

The basal layer of stratified epithelia mediate specialized adhesions to their underlying basement membrane. These specialized adhesions are referred to as hemidesmosomes. $\alpha_6\beta_4$ integrins are the only integrins present at hemidesmosomes, and function as critical transmembrane links between their ligand laminin 5 in the basement membrane and the keratin filament cytoskeleton within the cell. The cytoplasmic domain of the β_4 subunit plays an important role in this linkage (Fig. 8), by binding to the cytoskeletal linker proteins plectin and BP230, which, in turn, can bind directly to intermediate filaments. BP180

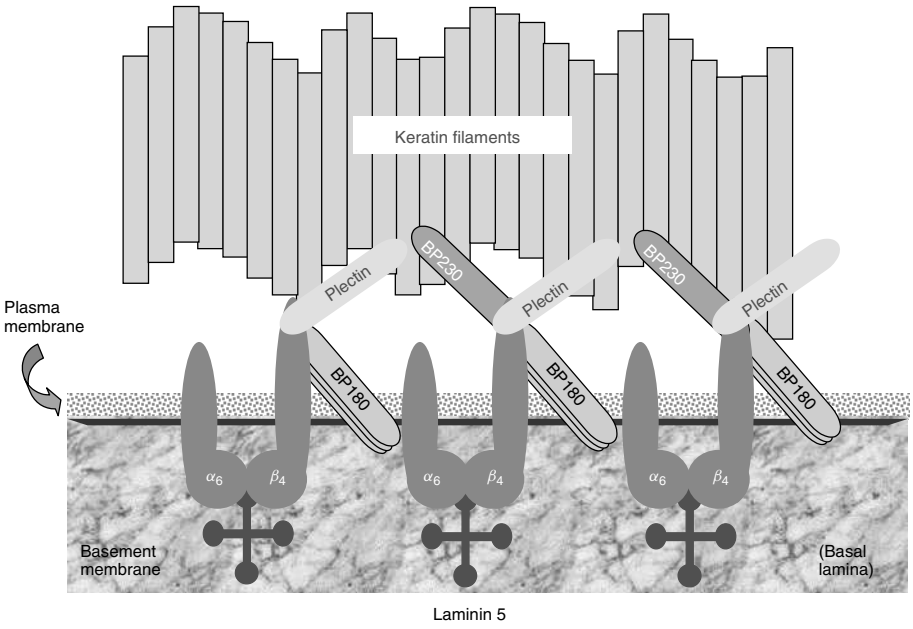

Fig. 8 Hemidesmosomes. Hemidesmosomes are sites of strong adhesion between cells and their underlying basement membrane. The $\alpha_6\beta_4$ integrin binds to its ligand laminin-5 in the basement membrane. The transmembrane protein BP180 has a collagenous extracellular domain that forms a trimer and associates with the basement membrane on the outside of the cell. The cytoplasmic domain of BP180 binds to the β_4 tail and plectin on the inside of the cell. Both plectin and BP230 function in linking $\alpha_6\beta_4$ to keratin filaments within the cell.

is another transmembrane protein that functions at hemidesmosomes. BP180 has a collagenous extracellular domain; its intracellular domain binds to the β_4 cytoplasmic domain.

The physiological importance of hemidesmosomal components is clear from studies of inherited human skin blistering disorders. In humans, loss of $\alpha_6\beta_4$ expression or laminin 5 expression causes a form of epidermolysis bullosa (EB). Patients with this disorder have very fragile skin, which is prone to extensive blistering due to a lack of normal hemidesmosomes. The adhesion of other epithelia is fragile as well, affecting organ function such as the intestines. Most patients suffering from this disorder survive only several months after birth at most. Mutations in the BP180 gene cause a less severe form of EB. Another form of EB results from mutations in the plectin gene; this form of EB is associated with muscular dystrophy indicating the importance of plectin function in other tissues.

Mice with null mutations in genes encoding hemidesmosomal components have similar phenotypes to those described for the corresponding human hereditary disorder. These null mice have been useful animal models for these diseases, providing important insights into the functions of hemidesmosome components. For example, the skin of plectin-null mice showed a reduced number of hemidesmosomes, and the hemidesmosomes present had fewer associated keratin filaments and exhibited reduced mechanical stability. Thus, plectin is not strictly required for the association of hemidesmosomes with keratin filaments. This is not true for BP230. Targeted deletion of BP230 in mice also results in a skin blistering phenotype. The number of hemidesmosomes present in the skin of BP230-null mice was similar to wild-type animals; however, the hemidesmosomes in BP230-null mice were not associated with keratin filaments. Thus, BP230 plays an essential role in connecting $\alpha_6\beta_4$ to keratin filaments at hemidesmosomes *in vivo*.

1.5.1 Assembly of Hemidesmosomes

Biochemical and molecular genetic approaches have been used to characterize protein interactions with the β_4 cytoplasmic domain and among the components of the hemidesmosome. Using these approaches, the β_4 cytoplasmic domain has been shown to bind directly to plectin, BP230 and the cytoplasmic domain of BP180. Other studies have shown that BP180 binds to plectin and BP230. The β_4 cytoplasmic domain has also been shown to associate with itself; the C-terminal region of the β_4 cytoplasmic domain binds to a site more toward the N-terminal that overlaps the binding site for plectin. This β_4 tail-β_4-tail interaction could potentially occur either intramolecularly or intermolecularly, and it has been suggested that the binding of plectin to the β_4 tail disrupts this interaction. The importance of individual interactions between the various hemidesmosomal components has been examined by testing the effect of expressing recombinant forms of these proteins, containing mutations that inhibit specific protein–protein interactions, on the formation of hemidesmosome-like structures on the basal cell surface of cultured epithelial cells. Emerging evidence from these types of studies suggests that the assembly of hemidesmosomes occurs by a stepwise process. An early step is the binding of plectin to the β_4 cytoplasmic domain. The next step is the recruitment of BP180, which requires the interaction of BP180 with both β_4 and plectin, as well as the association of plectin with the β_4 cytoplasmic

domain. Finally, BP230 is recruited. The recruitment of BP230 requires $\alpha_6\beta_4$ adhesions containing both BP180 and plectin. Thus, plectin appears to function in the assembly of hemidesmosomes by facilitating the interaction of BP230 and BP180 with the β_4 cytoplasmic domain and also by stabilizing the association of keratin filaments with hemidesmosomes.

1.5.2 Signaling by $\alpha_6\beta_4$

Like other integrins, $\alpha_6\beta_4$ can function as a signaling receptor. $\alpha_6\beta_4$ signaling impacts the survival, proliferation, and migration of epithelial cells. $\alpha_6\beta_4$ activates ERK MAP kinase that plays a critical role in regulating cell proliferation and survival. The β_4 cytoplasmic domain becomes phosphorylated on tyrosine residues when $\alpha_6\beta_4$ binds to laminin 5. These phosphorylations are important in linking $\alpha_6\beta_4$ engagement to the activation of intracellular signals. Although $\alpha_6\beta_4$ can signal in epithelial cells that do not form hemidesmosomes, it is not yet known whether $\alpha_6\beta_4$ integrins can activate signals when associated with intermediate filaments at hemidesmosomes. However, the activation of the epidermal growth factor (EGF) receptor can trigger the phosphorylation of the β_4 cytoplasmic domain resulting in the disassembly of hemidesmosomes, which is likely to be important for cell migration and proliferation. The $\alpha_6\beta_4$ integrin has been found to play a role in promoting cell migration and invasion of some carcinomas by activating PI 3-kinase, and the small GTP-binding proteins Rac and Rho. In cell culture models, $\alpha_6\beta_4$ integrin can promote cell migration on laminin 1 by associating with the microfilament cytoskeleton and stabilizing the adhesion of lamellipodia and filopodia to laminin1, suggesting that $\alpha_6\beta_4$ can function in both intermediate filament-associated and actin-microfilament-associated cell–matrix adhesions. The $\alpha_6\beta_4$ integrin is also expressed by the endothelial cells and neuronal cells. The adhesion complexes formed by $\alpha_6\beta_4$ in these cell types have not been fully characterized. However, it is known that $\alpha_6\beta_4$ associates with the intermediate filament cytoskeleton in endothelial cells and is likely to do so in neuronal cells as well.

In summary, members of the integrin family of cell adhesion receptors play important roles in most physiological processes. Integrins regulate these processes by providing a transmembrane connection between the various integrin ligands and components of the cell's cytoskeletal networks, and also functioning as signaling receptors in cooperation with other cell surface receptors.

2 Cell–Cell Junctions

2.1 Overview

Cell–cell junctions serve to bind cells together allowing for these cells to act as a tissue and mediate physiological functions within an organism. For example, cell–cell junctions in endothelial cells, which line the walls of all blood vessels, allow endothelial cells to regulate the movement of fluid, macromolecules, and immune cells from the vascular space to the extravascular space of tissues. Cell junctions are separated into groups according to their functions, and these groups include adhesive junctions, occlusive junctions and junctions that allow direct communication between cells. These junctions have been extensively studied in epithelial cells and are shown in Fig. 9. Adhesive junctions include desmosomes and adherens

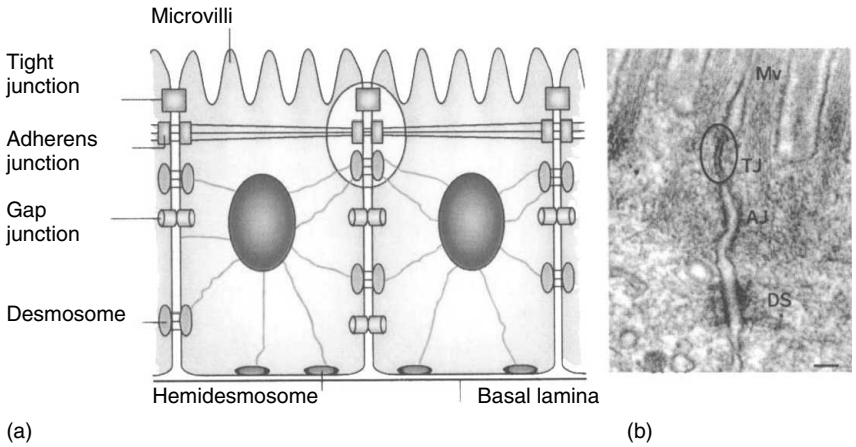

Fig. 9 Junctional complexes in epithelial cell monolayer. (a) Schematic showing the cellular location of tight junctions, adherens junctions, desmosomes, and gap junctions in an epithelial cell layer. (b) Electron micrograph of tight junctions (TJ), adherens junctions (AJ), and desmosomes (DS). Note the electron-dense regions associated with the plasma membrane in each junction. This is due to the localization of plaque proteins in these areas. (Reprinted with permission from Tsukita, S., Furuse, M., Itoh, M. (2001) Multifunctional strands in tight junctions, *Nat. Rev. Mol. Cell Biol.* **2**, 285–293).

junctions (AJs). Desmosomes are found primarily in tissues that experience mechanical stress, such as epithelial cells of the skin and myocardial cells of the heart. These junctions are connected to intermediate filaments and are thought to have mainly a structural function. AJs are connected to the actin cytoskeleton and also serve a structural function. Indeed, in certain epithelial cells such as those in the intestine, the AJ acts together with the actin cytoskeleton to allow contraction of the epithelial sheet. Occlusive junctions, also termed *tight junctions* (TJ), form restrictive barriers that regulate the paracellular flux of molecules across epithelial and endothelial monolayers, and act as a fence to prevent the movement of membrane components from the apical to the basal surface of a cell layer. Gap junctions allow for communication between cells. These junctions are formed by proteins called *connexins*. Connexins form a hexameric multimer that create a pore in the plasma membrane of the cell. The hexameric pore binds to a similar pore on an adjacent cell, thereby forming a continuous pore between cells that allows for the passage of ions and small molecules between neighboring cells. Gap junctions provide electrical and chemical coupling between cells whereas AJs, desmosomes, and TJs provide mechanical coupling between cells. The following discussion will focus on the junctions that provide mechanical coupling. A number of recent reviews provide further information on gap junctions and their role in cell–cell communication.

A common theme exists with respect to the structure of cell–cell junctions. All contain transmembrane proteins whose extracellular domains mediate binding to similar proteins on neighboring cells. The transmemebrane proteins of desmosomes and AJs are members of the cadherin

superfamily. Claudins, occludins, and junctional adhesion molecules (JAM) are all transmemebrane proteins that participate in the formation of TJs. The ultrastructures of TJs, AJs and desmosomes all display a dense plaque region adjacent to the plasma membrane when observed through an electron microscope. This region appears as a dense plaque due to the large number of adaptor proteins that form a complex that supports the function of the transmembrane proteins (Fig. 9b). The cytoplasmic domains of the transmembrane proteins bind to linker proteins that connect the transmembrane proteins to the cytoskeleton. In addition, both the cytoplasmic domain of the transmembrane proteins and the linker proteins can bind to and localize signaling proteins, such as the Src family of tyrosine kinases, to the junctional complex. Thus, as is the case in focal adhesions mediated by the integrins, cell–cell junctions too are now considered sites that mediate inside-out or outside-in signaling.

2.2 Cadherin Superfamily

In the early 1980s, two proteins were being investigated for their role in mediating cell–cell adhesion: uvomorulin and L-CAM. Upon sequencing of these proteins it was found that they shared a large number of amino acids and a number of structural features such as the requirement of calcium for cell–cell adhesion. These proteins became collectively known as E-cadherin. At this time, two other transmembrane proteins having a similar structure and amino acid sequence to E-cadherin were also identified: N-cadherin and P-cadherin. Most of what is known about cadherins has been learned from studies of E-, N-, and P-cadherin. To date, over 50 different cadherins have been identified in both vertebrates and invertebrates. The discovery of novel cadherin-like proteins, including the recent identification of the protocadherins, has lead to the formation of the cadherin superfamily containing cadherins and cadherin-related proteins.

All members of the cadherin superfamily possess cadherin homology repeats, referred to as EC domains, in their extracellular region. Cadherin-related proteins show a high degree of variability in the number of cadherin repeats in their extracellular domain with reported numbers ranging from 5 to 34. In addition, extracellular regions of cadherin-related proteins can contain structural motifs, such as laminin-A G repeats or EGF repeats, found in other proteins. A high degree of variability also exists with respect to the membrane-spanning region of cadherin-related proteins. Although most cadherin-related proteins contain a single spanning transmembrane region, some members contain seven membrane-spanning regions, while others are anchored to the plasma membrane by glysyl phosphotidylinositol (GPI) linkages. The cadherin-related proteins also show a diverse array of cytoplasmic tails with unique binding domains to a wide variety of molecules. The following discussion will not include cadherin-related proteins due to the variability of their structures and functions.

The other members of the cadherin superfamily have a number of identical structural features. These include five cadherin repeats in the extracellular domain, a single spanning transmembrane region, and a highly conserved cytoplasmic tail. In addition, these cadherins are synthesized as precursor molecules containing a signal peptide and a propeptide

region that are both removed by proteolytic cleavage.

Cadherins have been divided into five families on the basis of the domain structure and genomic organization of the cadherin proteins (Table 6). The five families are (1) the classical/type I cadherins; (2) the atypical/type II cadherins, the two families of desmosomal cadherins; (3) desmocollins; (4) desmogleins; and (5) a family containing only one member, BS-cadherin. Sequence similarities in the EC1 domain allow for classification of the different cadherins into families. Type I cadherins all have the triple amino acid sequence H-A-V in the first cadherin repeat (EC1). This sequence has been termed the cell adhesion recognition (CAR) sequence (Fig. 10), and as will be discussed, is required for cell–cell adhesion of type I cadherins. The other cadherin family members also have a central alanine in their CAR sequence, but the surrounding residues are different for each family. The HAV sequence has been found to interact with the N-terminal tryptophan (Trp2) residue also found in the EC-1 domain (Fig. 10). The amino acid sequence surrounding the Trp2 residue is also highly conserved within the type I cadherin family. If one looks at a sequence comparison surrounding the N-terminal

Tab. 6 Major cadherin subfamilies. (Adapted from Nollet, F., Kools, P., van Roy, F. (2000) Phylogenetic analysis of the cadherin superfamily allows identification of six major subfamilies besides several solitary members, *J. Mol. Biol.* **299**, 551–572).

Subfamily	*Protein name*	*Synonyms*
Classical/type I	Cadherin 1	E-cadherin, uvomorulin
	Cadherin 2	N-cadherin
	Cadherin 3	P-cadherin
	Cadherin 4	R-cadherin
	Cadherin 13	T- or H-cadherin
	Cadherin 15	M-cadherin
	EP-cadherin	C-cadherin (*Xenopus*)
Atypical/type II	Cadherin 5	VE-cadherin
	Cadherin 6	K-cadherin
	Cadherin 7	
	Cadherin 8	
	Cadherin 9	T1-cadherin
	Cadherin 10	T2-cadherin
	Cadherin 11	OB-cadherin
	Cadherin 12	Br-cadherin, N-cadherin 2
	Cadherin 18	Cadherin 14
	Cadherin 19	
	Cadherin 20	
Desmocollin	Desmocollin 1	
	Desmocollin 2	
	Desmocollin 3	
Desmoglein	Desmoglein 1	
	Desmoglein 2	
	Desmoglein 3	
BS Cadherin		

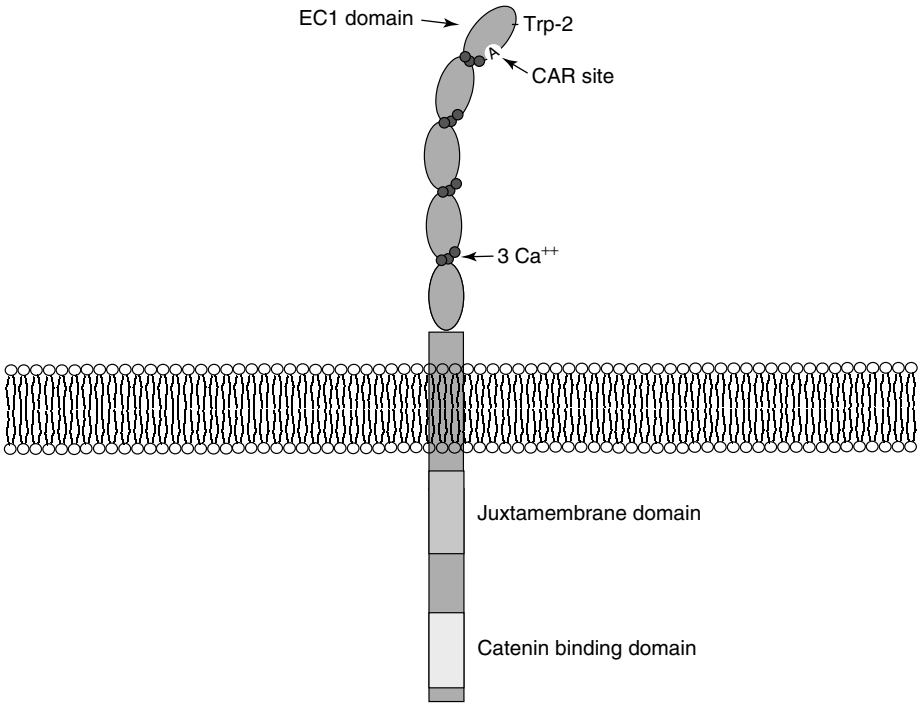

Fig. 10 Cadherin monomer. Schematic showing the important sites that are implicated in the regulation of cadherin-mediated adhesion, including the first cadherin repeat (EC1 domain), the N-terminal tryptophan (Trp2), cell adhesion recognition site (CAR site), calcium (Ca++) binding sites, the juxtamembrane region, and catenin binding domain.

Trp2 residue in the type II cadherins desmocollin and desmoglein, one also finds a high degree of sequence similarity within each type or family of cadherin. In addition to sequence similarities, genomic organization is also used to classify cadherins. For example, the precursor region and the cytoplasmic tail of atypical/type II cadherins are encoded by a single exon, whereas these regions in other cadherins contain one or more introns. The type II cadherins also contain two extra introns in the sequence coding the extracellular region that is not found in other cadherin families. On the basis of these structural and genomic similarities members of the cadherin family have been divided into families as shown in Table 6.

2.3 Type I/II Cadherins and Adherens Junctions

The binding of cadherins and the formation of stable AJs is a multistep process. The formation of cell–cell junctions by classical cadherins has been extensively studied in epithelial cells. In epithelial cells, cadherins are diffusely spread on the cell surface prior to cell–cell contact. Cells first approach one another through the formation of filopodia. As the filopodia from adjacent cells come into contact, cadherins form small clusters at the filopodia tip and recruit the proteins that promote cortical actin assembly. These clusters are brought into larger plaque-like structures as the cortical actin remodels. The binding

and formation of a mature cell–cell junction requires the following steps involving cadherins: (1) the binding of one cadherin to a second cadherin on the same cell, referred to as cis-dimer formation; (2) the binding of a cadherin on one cell to a cadherin on an adjacent cell, referred to as trans-dimer formation; (3) the formation of lateral complexes or clusters; and (4) the attachment of these complexes to the cytoskeleton to enhance the strength of the cell–cell attachment. The first two steps are mediated by the extracellular domain, whereas the last two steps occur through domains on the cytoplasmic tail.

2.3.1 Extracellular Domain: Cis- and Trans-cadherin Dimerization

The extracellular domain mediates cadherin–cadherin binding. The extracellular domain consists of five cadherin domains that form a rigid, rodlike structure through the binding of three calcium ions to the intervening sequence located at the base of each domain as shown in Fig. 10. Lateral cis-dimerization is the binding of two adjacent cadherins within the plasma membrane of one cell and is mediated by the interaction of the EC-1 and EC-2 regions of two cadherin molecules (Fig. 11). This process is thought to require the Trp2 and the hydrophobic pocket created by the HAV region on the EC-1domain. Indeed, crystallographic data has shown two possible scenarios for how these two peptide regions interact to establish the formation of a cadherin cis-dimer. In the first model, the Trp2 on one cadherin inserts into the hydrophobic pocket created by the HAV region on an adjacent cadherin. In the second model, the Trp2 inserts into the hydrophobic pocket on the same EC-1 domain resulting in a change in the conformation of the surrounding amino acids, which allows interaction with the EC-1 domain on an adjacent cadherin.

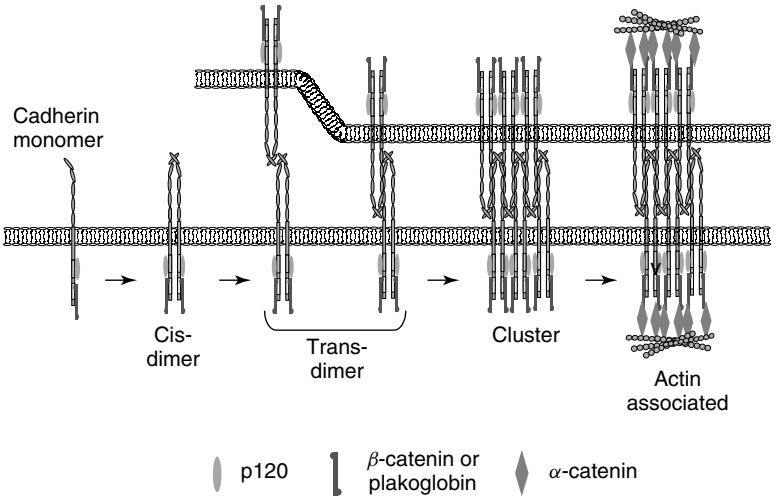

Fig. 11 Formation of cadherin-mediated cell–cell junction. Cadherin monomers first form cis-dimers through the interaction of the first two cadherin repeats. This is followed by formation of trans-dimers through the interaction of cadherin cis-dimers on adjacent cells. The trans-dimers then cluster, increasing the strength of cell–cell adhesion. The adhesion strength is increased further by the attachment of the cadherin–catenin complex to the actin cytoskeleton. (See text for details).

Interestingly, a recent crystallographic study using C-cadherin has suggested a third model in which cis-binding may actually form lateral multimers through interaction of EC-1/EC-2 domains on adjacent cadherins. Although the mechanism of cis-interaction of cadherins remains controversial, crystallographic, mutagenesis, and *in vitro* binding studies all support a requirement for cis-dimerization in cadherin-mediated cell–cell adhesion.

The structural basis involved in mediating homophilic binding of cadherins on adjacent cells is also fraught with controversy. As in cis-dimerization, trans-dimerization, which is the binding of two cadherins on different cells, has also been shown to require the EC-1 domain. In one model, the EC-1 domains of two cadherins on opposing cells bind to form a zipper-like structure as shown in Fig. 11. This model is supported by studies that have shown that the HAV motif and the amino acids surrounding this peptide mediate the specificity of cadherin adhesion. However, a trans-dimer with this structure seems too long to be accommodated in the intercellular space observed by electron microscopy. In a second model, the EC-1 domain of one cadherin interacts with the EC-4 or EC-5 domain of the cadherin on an adjacent cell. This model is consistent with the distance between plasma membranes observed by electron microscopy and is also supported by studies showing that antibodies to the EC-4 and EC-5 regions disrupt cadherin-mediated binding. In addition, direct force measurements would suggest that a greater overlap of the cadherins shown in Fig. 11 is required for maximum adhesive strength, and that interaction mediated only by the EC-1 domain would not be strong enough to maintain cell–cell adhesion. Nonetheless, both models support the formation of a zipper-like structure by the trans-interaction of cadherins on opposing cells.

Understanding the mechanisms of cadherin-mediated adhesion has important implications for therapeutic interventions in processes such as tumor angiogenesis. Monoclonal antibodies to the EC1 region of VE-cadherin have been shown to prevent branching morphogenesis of endothelial cells in culture and to inhibit angiogenesis in a mouse cornea model. Unfortunately, antibodies to the EC1 domain also cause a decrease in barrier function of confluent endothelial monolayers, particularly in the microcirculation of the lung. However, monoclonal antibodies to the EC4 domain inhibit angiogenesis, without altering the barrier function of endothelia with stable, well-structured AJs, such as those found in the lung. These results suggest that antibodies to the EC4 domain may be used to prevent angiogenesis and thus inhibit the growth of many tumors without having the adverse side effect of changing vascular permeability. These results further underscore the importance of understanding structure–function relationships that govern cadherin-mediated cell–cell adhesion.

Using cell culture aggregation assays, it was demonstrated that the EC1 domain and the HAV region play essential roles in determining the specificity of homophilic binding of classical cadherins. In early studies, E-cadherin and P-cadherin were expressed as recombinant proteins in fibroblasts that normally do not express these cadherins and do not demonstrate calcium-dependent cell–cell adhesion. These studies demonstrated that when cells expressing E-cadherin were mixed with cells expressing P-cadherin, the resulting cell aggregates would contain either E-cadherin cells or P-cadherin

cells but not a mixture of the two. Mutational studies demonstrated that the EC1 domain and the amino acids surrounding the HAV peptide play an important role in homophilic trans-cadherin adhesion. Further studies using domain-swapping approaches, antibodies or peptides to the EC1 domain confirmed these findings. Interestingly, recent studies have suggested that cadherins may not be restricted to homophilic binding, but may also interact with each other in a heterophilic manner. This is particularly true of the type II cadherins. The members of this family of cadherins have been shown to bind in a heterophilic manner to other members of the same family. For example, cadherin 8 can bind to cadherin 11 allowing for the formation of cell aggregates with strong cell–cell adhesion. One should remember that type II cadherins do not contain the HAV sequence and do not bind at all to type I cadherins. Recent studies have found that heterophilic binding may also occur within the type I cadherin family; however, the studies have suggested that these heterophilic interactions are weaker than homophilic interactions. As the studies demonstrating heterophilic binding of cadherins have been performed only in cell culture systems, the physiological relevance of heterophilic binding in tissue and organ function is unknown.

2.3.2 Cytoplasmic Domain: Lateral Clustering and Cytoskeletal Attachment

Changes in the strength of cadherin-mediated adhesion are necessary for the dynamic cellular movements found during processes such as angiogenesis and tissue morphogenesis. Environmental signals, such as growth factors, act to modulate the strength of cadherin-mediated adhesion by changing the association of cadherin with the actin cytoskeleton and by disrupting cadherin clustering. Both of these processes are regulated through the cadherin cytoplasmic tail. The cytoplasmic tail of cadherin contains two important domains, the juxtamembrane domain (JMD) and the C-terminal catenin binding domain (CBD), both of which bind to the catenins to form a cadherin–catenin complex. The catenins are a family of related proteins that share a central domain called the armadillo-repeat domain (ARM domain). This domain contains 10 to 13 armadillo repeats, so named because of their sequence homology to the armadillo gene product first identified in *Drosophila*. The ARM repeats have been shown to have a tertiary structure that results in the formation of a groove that contains a number of positively charged residues. Proteins that bind to the ARM region do not possess a single consensus sequence, but do possess many negatively charged amino acids that bind within the positively charged groove created by the ARM domain.

The extracellular domain of cadherin can support cell–cell adhesion independent of the cytoplasmic tail, but the strength of adhesion is considerably weaker than that supported by the full-length molecule. The binding mediated by the extracellular domain of cadherins can be increased by clustering cadherin extracellular domains on the cell surface. This was shown using chimeric cadherin molecules containing an intracellular regulatable oligomerization motif connected to the extracellular and transmembrane domain of cadherins. Under normal conditions, the JMD of the cytoplasmic tail is believed to regulate cadherin clustering. Deletion mutants of cadherin that contain the JMD, but not the CBD, were found to cluster and mediate strong adhesion demonstrating the importance of the JMD in regulating cadherin function.

The interaction of the JMD with p120 catenin has been implicated in regulating lateral clustering and the strength of cadherin-mediated cell–cell adhesion. p120 is a member of the p120 family, which includes p120, p0071, δ-catenin, and AVRCF. These proteins have greater than 45% identity in the ARM domains and bind to cadherins via the interaction of the ARM domain with a highly conserved region in the JMD. The most extensively studied member of this family to date is p120. Initial studies presented conflicting results concerning the effect of p120 on cadherin function with one study showing that the p120 cadherin interaction was required for lateral clustering and enhanced the strength of cell adhesion, while a second study presented contrasting data suggesting that the JMD and its interaction with p120 had a negative effect on cell–cell adhesion. This discrepancy was attributed to differences in the phosphorylation state of p120 in the different cell types that were used for these studies. Indeed, phosphorylation of p120 on serine and threonine residues in the N-terminus results in a decrease in cell–cell adhesion, whereas inhibition of phosphorylation of these residues using staurosporin, or deletion of the N-terminus results in an increase in cadherin-mediated cell–cell adhesion. In addition to containing serine/threonine phosphorylation sites, the N-terminus of p120 also contains a number of tyrosine phosphorylation sites. Although the phosphorylation of p120 has been shown to alter cadherin function, the molecular mechanism responsible for the change in cadherin function with phosphorylation of p120 has not been reported.

The interaction of p120 with the JMD has been implicated in mediating a number of functions in addition to cadherin clustering. For example, the juxtamembrane region of VE-cadherin has been implicated in excluding N-cadherin from cell–cell junctions in cells expressing these two cadherins, which may be why N-cadherin is not observed at cell–cell junctions in endothelial cells. The interaction of JMD with p120 has also been shown to protect E-cadherin from degradation. The colon tumor cell line SW48 possesses a defect in the p120 gene that prevents expression of p120. These cells show minimal expression of E-cadherin and have poor cell–cell adhesion. Interestingly, restoring the levels of p120 increased both the E-cadherin levels and E-cadherin-mediated cell–cell adhesion. We have found similar results in endothelial cells, where a decrease in the level of p120 results in a decrease in the level of VE-cadherin and a decrease in endothelial monolayer integrity. Thus, interaction of p120 with the JMD region of at least some cadherins is required for the expression at the plasma membrane.

The C-terminus of the cytoplasmic tail contains the CBD and mediates attachment to the actin cytoskeleton through binding to β-catenin, plakoglobin (also known as γ-catenin), and α-catenin. Plakoglobin and β-catenin share a similar structure containing 12 ARM repeats found in the central ARM domain that is flanked on either side by N-terminal and C-terminal domains. The binding of β-catenin and plakoglobin to cadherins is mediated through the ARM domains, and these two proteins bind to the CBD in a mutually exclusive fashion. Attachment to the cytoskeleton is then achieved by the binding of α-catenin to the N-terminus and the first ARM repeat of plakoglobin or β-catenin and to actin. In addition to binding directly to the actin cytoskeleton, α-catenin can also mediate attachment to microfilaments by binding to actin-associated

proteins, such as α-actinin, vinculin, or ZO-1.

Disruption of the binding of β-catenin/plakoglobin to either cadherin or α-catenin regulates changes in the strength of cell–cell adhesion and has been suggested as playing a physiological role in cell functions requiring dynamic changes in cell–cell adhesion, such as the migration of leukocytes through the endothelium lining the blood vessel wall. In addition, disruption of cadherin attachment to the actin cytoskeleton has been implicated in disease states such as cancer. Tumor cells deficient in α-catenin, but expressing E-cadherin and β-catenin, have a high rate of proliferation and display a highly invasive phenotype. Expression of α-catenin in these cells will restore the attachment of cadherins to the actin cytoskeleton and reverse the proliferative and invasive phenotype. Attachment to the actin cytoskeleton also is important for the contraction of epithelial cell sheets, a process that is required for the formation of various structures during development. Indeed, mutations in α-catenin result in trophoblast malformation and inhibition of development at the blastula stage due to loss of intercellular adhesion.

In addition to performing structural and regulatory roles at the AJ, catenins have also been implicated in transcriptional regulation of gene expression. A number of catenins including p120 family members, plakoglobin, and β-catenin have been found in the nucleus. Although the role of many of these catenins in the nucleus is not fully understood, transcriptional regulation by β-catenin has been shown to be part of the TCF/LEF signaling pathway. The majority of the β-catenin in a cell is found in the AJ and any free β-catenin is usually rapidly degraded through a complex series of reactions that lead to the ubiquitin-proteasome pathway. However, activation of the Wnt signaling pathway results in the stabilization of cytoplasmic β-catenin that then translocates into the nucleus. Once in the nucleus, β-catenin complexes with LEF/TCF transcription factors, and activates the LEF/TCF target genes that encode proteins involved in cell proliferation, apoptosis, and remodeling of the extracellular matrix. Increases in β-catenin nuclear signaling, owing to a loss of AJs coupled with activation of the Wnt pathway, have been implicated in cancer progression. Although a similar pathway has not been elucidated for other catenins, many have been found to bind to transcription factors, suggesting that they may also participate in transcriptional activation and further support the association between the AJ and regulation of gene expression.

2.3.3 Regulation of Cadherin–Catenin Complex

The phosphorylation of serine, threonine, or tyrosine residues on β-catenin, plakoglobin, and the CBD of cadherin has also been implicated in regulating the association of cadherins with the actin cytoskeleton. A number of studies have found that receptor tyrosine phosphatases such as PTPμ are part of the cadherin–catenin complex, possibly binding directly to cadherins. Activation of Src kinases, interaction with receptor tyrosine kinases, such as Erb-2 and EGF receptors, or the addition of phosphatase inhibitors, all result in an increase in the phosphorylation of β-catenin or plakoglobin. Numerous studies have found that increases in the phosphorylation of β-catenin, plakoglobin and cadherin are associated with decreases in cell–cell adhesion and a disruption of cadherin β-catenin α-catenin complex. However, these studies

did not examine the effect of phosphorylation of specific amino acid residues on the disassembly of the cadherin–catenin complex. More recent investigations have begun to examine the role of individual amino acids of β-catenin. Mutation of tyrosine 654 in β-catenin was found to prevent the dissociation of β-catenin E-cadherin complexes triggered by exposure to the phosphatase inhibitor sodium orthovanadate, thereby demonstrating a cause-and-effect relationship between phosphorylation of this residue and cadherin binding. Similarly, phosphorylation of β-catenin on Tyr142 was found to decrease its association with α-catenin. Interestingly, this tyrosine residue is phosphorylated by Fer or Fyn tyrosine kinases that can both bind to p120. Thus, p120 may regulate β-catenin α-catenin association by recruiting these kinases to cadherin complexes. The further study of recombinant cadherins and catenins with mutations that target individual tyrosine, serine, and theosine residues will provide important insights into how phosphorylation regulates cell–cell adhesion at the AJ.

Rho, Rac, and Cdc42 are members of the Rho GTPase family that regulate changes in the actin cytoskeleton and play a major role in cell processes that require actin reorganization. Given the close association of cadherin function with attachment to the actin cytoskeleton, it is not surprising that the small GTPases Rac, Rho, and Cdc42 have all been implicated in regulating cadherin-mediated adhesion. Use of dominant negative or constitutively active forms of these small GTPases has shown that each can influence the state of cadherin-mediated adhesion, with Rho and Rac being required for stable localization of cadherins at cell–cell contacts in epithelial cells. Recent investigations have also begun to elucidate the role of Rho GTPases in signaling pathways initiated by cadherin binding. These studies have found that Rac is activated upon engagement of cadherins and is recruited to nascent cadherin-mediated adhesion sites. Rac is eventually lost from AJs as they mature, indicating that although Rac is activated upon contact formation, it is not continually activated by cadherins. Rac may increase the strength of cadherin-mediated cell–cell adhesion via its influence on IQGAP. IQGAP is localized to the cell–cell junction by binding to β-catenin at the same site as α-catenin, suggesting that binding of IQGAP prevents attachment to the actin cytoskeleton. Activation of Rac disrupts the binding of IQGAP to β-catenin resulting in an increase in α-catenin β-catenin association and an increase in cadherin attachment to the actin cytoskeleton. In addition, Rac activation also results in the localization of the Arp 2/3 complex at cadherin-mediated cell–cell junctions. The Arp 2/3 complex initiates actin assembly and may be required for actin polymerization that results in the expansion of cell–cell contacts.

The function of Rho has been more elusive. Studies have reported that Rho is activated upon cadherin binding while others have found inhibition of activity with cadherin binding. This discrepancy may be due to the different cell types used in these studies, as the effect of small GTPases on cadherin-mediated junctions is dependent on cellular context. For example, VE-cadherin does not require Rac or Rho activity to localize to the cell–cell junction in endothelial cells. However, when VE-cadherin is expressed in CHO cells, localization of VE-cadherin to cell–cell junctions is Rho-dependent. This study underscores the difference between endothelial cell and epithelial cell junctions and shows the importance

of choosing the appropriate cell type for investigating specific cell functions involving the regulation of cadherin-mediated adhesion.

2.3.4 Other Components of Adherens Junctions: Nectin and Afadin

In addition to the cadherin–catenin complex, the AJ of many cell types including epithelial cells, neurons and sertoli cells contain a nectin/afadin complex that also anchors to the actin cytoskeleton. Nectins are a family of transmembrane proteins that are highly homologous to human poliovirus receptor. There are 4 isoforms of nectin with nectin 1, 2, and 3 having two to three splice variants. The extracellular domain of nectin contains three Ig-like domains. There is a single pass transmembrane region coupled to a carboxyterminal cytoplasmic tail that, in most nectins, binds to the PDZ domain of afadin. Similar to cadherins, nectins form cis-dimers in the lateral plane of the membrane prior to forming trans-dimers. Cis-dimerization is regulated by the second Ig-like domain in the extracellular region, while the first Ig-like domain is responsible for trans-dimer formation. In contrast to cadherins, trans-dimerization in nectins is calcium independent; however, nectins can form both homo- and hetero-trans dimers.

Afadin is a cytoplasmic protein that binds to the C-terminus of nectin. There are two isoforms of afadin – ''s'' and ''l.'' L-afadin contains a number of domains, including a Ras association domain, forkhead association domain, DIL domain, PDZ domain, three proline-rich regions, and an actin binding domain at the C-terminus. The ''s'' isoform contains these same domains; however, the C-terminus is deleted removing the third proline-rich domain and the actin binding region. L-afadin can bind to the side of actin filaments, but not to the ends, thereby linking nectin to the actin cytoskeleton. Afadin has been found to play an important role in development, as knocking out this gene results in embryonic lethalality at day 10.5. These embryos show defects at gastrulation including disorganization of the ectoderm, impaired migration of the mesoderm, and a loss of somites. Interestingly, in afadin−/− embryos the E-cadherin localization was disrupted in the ectodermal cell layer, but was localized to cell–cell junctions in the endodermal layer. This suggests that the nectina fadin complex may be required for the formation of cadherin-mediated junctions in certain cell types. This is supported by studies showing that the formation of nectin-mediated junctions will recruit E-cadherin, and the formation of cadherin-mediated junctions will recruit nectins. The recruitment of E-cadherin by nectin or nectin by E-cadherin requires afadin and α-catenin. Although afadin and α-catenin do bind to one another, the interaction is weak, leading investigators to believe that an intermediate protein may be required for the interaction of E-cadherin and nectin in the AJ.

2.4 Desmosomal Cadherins and Desmosomes

Desmosomes are spot weldlike structures that provide strong cell–cell adhesion to tissues that require adhesive strength to maintain organ function. When observed by electron microscopy, desmosomes have a very distinctive ultrastructure consisting of two electron-dense plaques surrounding a lighter central core (Fig. 12a). The central core region contains the plasma membranes and the extracellular domains of the desmosomal cadherins from each of the two connected cells. Each electron-dense band is actually a tripartite structure

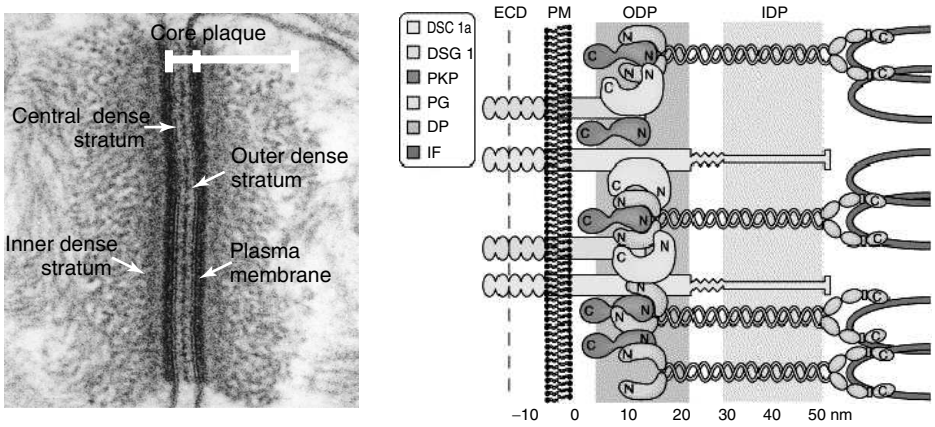

Fig. 12 Ultrastructure of desmosomal junction. (a) Electron micrograph showing the ultrastructure of a desmosome. The core region is the intercellular space between the plasma membranes of adjacent cells. The plaque regions contain proteins whose interactions serve to anchor the desmosome to intermediate filaments. The electron micrograph was kindly provided by Andrew Kowalczyk. (b) Schematic of desmosomal components. The cytoplasmic tail of desmocollins (Dsc) and desmoglein (Dsg) bind to plakoglobin (PG), plakophilin (Pkp), and the amino-terminus of desmoplakin (Dsp) in the outer dense plaque (ODP). The C-terminus of Dsp binds to the intermediate filaments. (Reprinted with permission from Leung, C.L., Green, K.J., Liem, R.K.H. (2002) Plakins: a family of versatile cytolinker proteins, *Trends Cell Biol.* **12**, 37–45).

with an outer dense plaque located next to the plasma membrane, a translucent middle region, and an inner dense plaque bordering the cytoplasm. Intermediate filaments converge on the desmosome, forming loops that pass into the inner dense plaque. The dense plaques are sites containing a high density of proteins that serve to attach the desmosomal cadherins to the intermediate filaments.

Desmosomes contain cadherins from two families – the desmocollins (Dsc) and the desmogleins (Dsg), with Dsc having three isoforms and Dsg having four isoforms. Dsg2 and Dsc2 are the most widely distributed of the desmosomal cadherins found in simple epithelia, the basal layer of epidermis, and in myocardium, all of which are tissues that require cell adhesive strength for a highly resilient junction. Indeed, in the myocardium these cadherins are localized to the intercalated discs that connect adjacent cardiac myocytes to one another. Dsg3 and Dsc3 are localized to the basal and suprabasal layers of epidermis and stratifying epithelia. Dsg1 and Dsc1 have the most limited distribution and are found in the highly differentiated upper layers of the epidermis. The importance of desmosomes to the maintenance of skin integrity is demonstrated by *Pemphigus foliaceus* and *Pemphigus vulgaris*, two autoimmune blistering diseases that result from the generation of antibodies to Dsg1 or to Dsg3 respectively.

2.4.1 Extracellular Domain of Desmoglein and Desmocollin

The structural organization of the extracellular domain of desmosomal cadherins

is similar to that of type I/II cadherins, although major differences exist in the sequences of the five cadherin repeats. The EC1 domain has the well-conserved tryptophan as its second amino acid and the surrounding AA sequence (10 mer) for each family is well conserved. The desmosomal cadherins also posses a CAR site with a central alanine. The surrounding AA differ from those in classical cadherins, but again are conserved within the desmogleins (Dsg1 R-A-L, Dsg2 Y-A-L, Dsg3 R-A-L) and the desmocollins (Dsc1a Y-A-T, Dsc2a FAT, Dsc3a Y-A-S). The CAR site for Dsg/Dsc has been shown to play a role in the trans-adhesion of the desmosomal cadherins; however, as with the type I and II cadherins, there is confusion on whether the desmosomal cadherins bind in a strict homophilic or heterophilic manner.

To determine the manner by which these two cadherin families mediate cell–cell adhesion, Dsg or Dsc were expressed in fibroblasts that do not express endogenous cadherins. These early studies demonstrated that the expression of a single desmosomal cadherin would not support cell–cell adhesion, but the expression of certain Dsg/Dsc pairs resulted in the formation of cell aggregates. These studies also demonstrated that in addition to requiring specific Dsg/Dsc pairs, specific cytoplasmic proteins must also be expressed in order to achieve strong cell–cell adhesion. Interestingly, the addition of CAR peptides homologous to either Dsg or Dsc of the Dsg/Dsc pairs was able to prevent cell–cell adhesion suggesting that Dsg/Dsc bound in a heterophilic manner. Coimmunoprecipitation of Dsc and Dsg further supported the concept that these cadherins bind in a heterophilic manner. However, more recent studies have indicated that CAR peptides homologous to both the Dsg and the Dsc are required in order to inhibit epithelial morphogenesis in tissues expressing Dsg2 and Dsc2, or Dsg3 and Dsc3, suggesting that homophilic interactions are involved in the *in vivo* function of desmosome cadherins during epithelial morphogenesis. Thus, current evidence suggests that a combination of heterophilic and homophilic interactions may participate in cell–cell adhesion at desmosomes.

2.4.2 Cytoplasmic Tail, Plaque Proteins, and Attachment to the Cytoskeleton

The cytoplasmic tails of Dsg and Dsc exhibit distinct structural features. The cytoplasmic tail of Dsc is much shorter than that of Dsg and has two forms as a result of alternative splicing. The ''a'' form has a CBD that binds to plakoglobin but not to β-catenin. The CBD is replaced in the ''b'' form of the cytoplasmic tail with an insertion of 11 amino acids not found in the ''a'' form resulting in the inability of the ''b'' form to bind to plakoglobin. Although Dsc-b does not bind plakoglobin, this desmosomal cadherin can still link to the cytoskeleton, as it can bind to desmoplakin (DP) and plakophilin-3, two proteins that also link to intermediate filaments. As in Dsc, the cytoplasmic domain of Dsg contains a CBD that binds to plakoglobin but not to β-catenin. This is followed by a proline-rich linking region, a repeated unit domain (RUD), and a terminal glycine rich domain (DTD). The cytoplasmic tail of Dsg does not bind directly to DP. Interestingly, the cytoplasmic regions of Dsc and Dsg behave differently when expressed as recombinant proteins lacking the extracellular domain. Indeed, deletion mutants containing only the cytoplasmic domain of Dsc-a can recruit DP and intermediate filaments to the plasma

membrane, whereas the Dsg cytoplasmic tail acts as a dominant negative that prevents the formation of desmosomes. The dominant negative activity of the Dsg cytoplasmic tail can be reversed by mutating the CBD. The mechanism of this response is not known but the indications are that the interaction of Dsg/Dsc with intermediate filaments is more complex than just direct structural connections through plaque proteins.

As described previously, plakoglobin is a member of the armadillo family of proteins, which links type I and type II cadherins to α-catenin, thereby supporting attachment to the actin cytoskeleton. In desmosomes, plakoglobin binds to the CBD of Dsc and Dsg. Interestingly, the binding site for Dsc/Dsg on plakoglobin overlaps with the binding site for α-catenin (the first ARM repeat); thus, the binding of plakoglobin prevents the association of α-catenin with the desmosomal cadherins. Instead of binding to α-catenin, plakoglobin binds directly to DP, and appears to play an important role in linking the desmosomal cadherins to DP and the intermediate filament cytoskeleton. The C-terminus of plakoglobin has also been found to play a role in regulating desmosome structure, as mutation of this region results in desmosome fusion and the formation of desmosomes that cover a large area of the plasma membrane. The importance of plakoglobin to the function of desmosomes *in vivo* has been demonstrated by gene ablation experiments in mice. Plakoglobin-null mice exhibit early embryonic lethality due to mechanical defects in the heart that render the organ unable to withstand the hemodynamic forces generated by cardiac muscle contraction. At the ultrastructural level, there is a loss of intercalated disc integrity, and the normal organization of desmosomal structures is disrupted. Interestingly, the plakoglobin-null phenotype is not fully penetrant, and survivors exhibit skin defects (fragility and blistering) even though desmosomes in most tissues appear morphologically normal.

In addition to plakoglobin, a second family of armadillo proteins is found in desmosomes. The plakophilins (PKP) are ARM proteins belonging to the p120 subfamily. In humans, three distinct plakophilin isoforms arise from three different genes. The first human genetic disorder to be attributed to a desmosomal gene was a mutation in plakophilin-1. Plakophilin-1 mutations lead to a skin fragility and dysplasia syndrome, resulting in epidermal blistering. The plakophilins exhibit a tissue- and differentiation-specific expression pattern and, depending on the tissue, the plakophilins can localize to both desmosomes and to the nucleus. In desmosomes, PKP-1 is found in the upper, most differentiated layers of stratified epithelia, and PKP-2 is found in the basal cell layers of stratified epithelia. PKP-2 is also found in some single-layered epithelia. Recently, plakophilin 3 has been implicated as playing a central role in desmosomal structure owing to its multiple binding partners and its widespread distribution in different epithelial cells. PKP-3 has been found to bind to all three Dsgs and to Dsc3a and 3b, as well as to Dsc1a and Dsc2a. In addition, PKP-3 was found to bind to plakoglobin, DP, and epithelial keratin-18. Interestingly, this study was unable to find PKP-3 in the nucleus, suggesting that it may play a more structural role than PKP-1 and -2. In contrast, plakophilin-1 and -2 exhibit strong nuclear localization, and plakophilin-2 has been shown to interact with the RNA polymerase III. Furthermore, PKP-2 has recently been found to participate in transcriptional regulation in

conjunction with β-catenin. These findings suggest that plakophilin-1 and -2, much like β-catenin and p120, may play dual roles in the cell: a structural role at the desmosome and a transcriptional role in the nucleus.

Desmoplakin (DP) is the protein that plays the central role in linking the desmosomal cadherin complex to intermediate filament networks. There are two closely related isoforms of DP resulting from alternative splicing, DP1-322 kD and DP2-259 kD. Both forms are found in all tissues except in the heart where only DP1 is located. DP is a dumbbell-shaped molecule that possesses three domains, an N-terminal globular domain, a coiled-coiled rod domain, and a carboxyterminal globular domain, and bind to intermediate filaments. DP is part of a large family of cytoskeletal linking proteins termed the plakin family of cytolinkers. The founding members of this family include DP, the hemidesmosomal protein BPAG-1 (BP230) and plectin, a cytoskeletal cross-linking protein with a wide tissue distribution. This family of proteins is defined by an amino-terminal plakin domain, which appears to contain protein interaction motifs that target individual plakin family members to specific subcellular destinations. In the case of DP, the N-terminal region of this protein has been shown to bind to plakoglobin, plakophilin, and Dsg/Dsc. The coiled-coiled rod domain of DP is believed to be responsible for dimerization (possibly multimerization). The length of this region is variable; DP-1 contains 599 AAs more than DP-2. The last region contains three globular plakin domains that are responsible for binding to intermediate filaments.

As shown in Fig. 12(b), DP plays a central role in the desmosome as it is the primary protein that connects to the intermediate filaments. Gene knockout studies have reinforced the importance of DP to desmosome function. Initial gene knockout studies found that loss of DP was lethal at day E5.5 to 6.5 due to a loss of DP in extra-embryonic tissue surrounding the embryo. The function of the extra-embryonic tissue was rescued using an approach that allows the extra-embryonic tissue to have a wild-type genotype, while the developing embryonic tissue contains the DP knockout. This approach allowed development until embryonic day 10. As expected, defects were found in the heart and the skin, organs known to require strong cell–cell adhesion to maintain tissue integrity. The neuroepithelium, found in the head folds and in the lining of the spinal cord, was also affected by the loss of DP. Prior to neural tube closure there is normally an increase in desmosomes followed by a loss of these junctions once the neural tube is formed. In DP−/− embryos, the neural tube was collapsed and the neuroepithelium was disorganized. Interestingly, the loss of DP did not affect differentiation of the neuroepithelium but prevented the stabilization and/or completion of neural tube formation.

The DP knockout animal also displayed fewer capillaries than wild-type mice. Interestingly, endothelial cells do not contain desmosomes. Instead, plakoglobin and DP bind to VE-cadherin (cadherin-5) forming a structure called the *complexus adherens junction* or *syndesmosome*. This junction has been observed in the microcirculation *in vivo*, but does not appear to be present in large-vessel endothelium. In DP−/− embryos, only the capillaries appeared to be disrupted, while the large vessels appeared to develop normally. In addition, the DP−/− phenotype resembles the VE-cadherin phenotype (−/−); both

exhibit lethality at embryonic day 9.5 due impaired remodeling and maturation of blood vessels. *In vitro* studies also support the roles of plakoglobin and DP in attaching VE-cadherin to intermediate filaments, as expression of these three components of the complexus AJ will induce the formation of cell–cell junctions in fibroblasts. One should note that, to date, VE-cadherin is the only cadherin from the type I and type II families to form attachments to intermediate filaments and the actin cytoskeleton. Thus, VE-cadherin is a very unique member of the cadherin superfamily.

2.4.3 Functions of Desmosomes

The previous discussion highlights the importance of desmosomes in the maintenance of tissue integrity. However, recent studies suggest that desmosomes may mediate other functions in addition to providing strong cell–cell adhesion. For example, desmosomal adhesion has been implicated in morphogenic cell positioning in the mammary gland. *In vivo*, the luminal epithelial cells of the mammary gland possess desmosomal adhesions mediated by Dsg2/Dsc2, while the myoepithelial cells surrounding the luminal cells have desmosomes containing Dsg3/Dsc3 in addition to Dsg2/Dsc2. Isolating these cells from tissue and allowing them to recombine in culture results in the formation of aggregates in which the Dsg3/Dsc3 myoepithelial cells surround the luminal epithelial cells. The addition of CAR peptides homologous to Dsg3/Dsc3 inhibited the correct association of these cells, suggesting that Dsg3/Dsc3-mediated adhesion is required for the sorting of mammary epithelial cells into appropriate cell layers.

In addition to regulating morphogenesis, desmosomes may also play a role in regulating differentiation. Recent studies demonstrated that the ratio of Dsg1 to Dsg3 expression varies in different epithelial tissues and that this ratio is important in regulating the differentiation of these tissues. For example, Dsg1 is expressed in all layers of the stratified epithelial layers of the skin, whereas Dsg3 is expressed only in the suprabasal layer. In contrast, Dsg1 and Dsg3 are expressed in all cell layers of the stratified epithelia of the oral mucosa. Using a transgenic approach, Dsg3 was expressed in all epithelial cell layers of the mouse skin producing a Dsg1 : Dsg3 ratio similar to that in the oral mucosa. Interestingly, the stratum corneum, the outermost layer of the skin of these transgenic mice, now had a histological appearance similar to that of the oral mucosa. Furthermore, the skin of these mice had excessive transepidermal water loss that resulted in death due to dehydration, indicating that the Dsg3/Dsg1 ratio is also important in the regulation of barrier function.

2.5 Tight Junctions

Tight junctions form a meshwork of interconnected strands grouped in a narrow belt at the apical region of epithelial or endothelial cell–cell adhesion. These structures have been studied primarily in epithelial cells whose monolayers form vital cell barriers that tightly regulate the movement of fluid and molecules between different tissue compartments. In addition to regulating paracellular transport, TJs separate the apical plasma membrane from the basal plasma membrane, and thus act as a fence to maintain the different lipid and protein compositions of these two cell surfaces. At the ultrastructural level, the plasma membranes of two

adjacent cells come into such close proximity that the outer leaflets of the adjacent plasma membranes appear to be fused. The anastomosing filaments of tTJs are best observed using freeze fracture as shown in Fig. 13(a). Freeze fracture is a platinum carbon replica of a fractured membrane surface that provides a three-dimensional relief of the junction when viewed by scanning electron microscopy. This technique creates an image of either strands of beads on the protoplasmic face or grooves on the exoplasmic face.

Early hypotheses speculated that the tight junction may be formed by specialized lipid arrangements between the two plasma membranes of adjacent cells; however, more recent studies have shown that transmembrane proteins are responsible for the ultrastructure of the tight junction (Fig. 13c). In a manner similar to AJs and desmosomes, the transmembrane proteins of TJs attach to the cytoskeleton through linker proteins and contain scaffolding proteins that allow TJs to participate in a number of signal transduction pathways.

2.5.1 Claudins and Other TJ Transmembrane Proteins

Initial studies using transepithelial electrical resistance (TER) to assess the barrier function of an epithelial monolayer suggested a relationship between the number of tight junction strands and TER. However, this concept was challenged by studies using Madin-Darby canine kidney (MDCK) epithelial cells, a cell line that is used extensively for *in vitro* studies of the epithelial barrier as they form functionally intact TJs. Interestingly, two strains of MDCK cells had been identified that had vastly different TERs (MDCK I $\sim$3000 Ωcm^2 and MDCK II $\sim$100 Ωcm^2), but possessed the same number of tight junction strands with the same morphology. This suggested that in addition to the number of tight junction strands, the

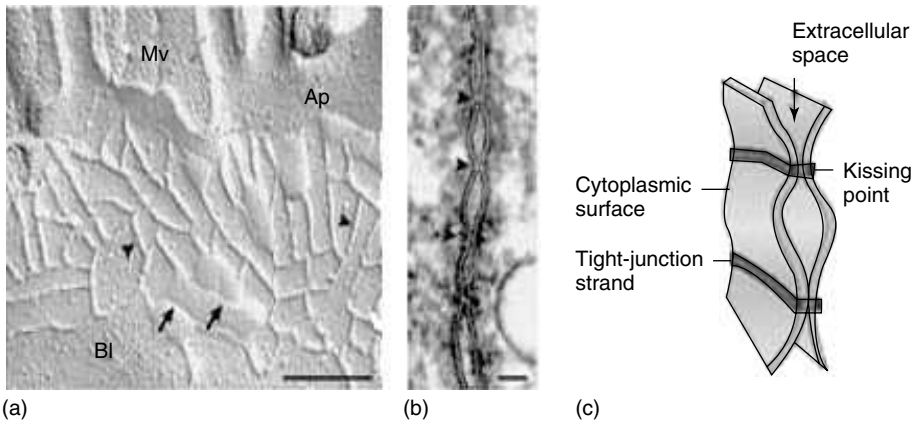

Fig. 13 Ultrastructure of tight junctions. (a) Electron microscopic image showing freeze-fracture replica of the tight junctions in intestinal epithelial cells. The interconnected strands appear as fibers on the P-face (arrow heads) and as grooves on the E-face (arrows). (b) Electron micrograph showing the close association of the plasma membranes in tight junction strands. Note the dense plaque region associated with the junction. protein composition of the tight junction strand may control the selectivity of the epithelial barrier. In 1998, two novel integral membrane proteins, claudin 1 and claudin 2, were identified from TJ enriched fractions. When expressed in fibroblasts, these proteins were able to produce TJ strands that were morphologically similar to those of epithelial cells. Since that time, over 20 claudin isoforms have been identified. Claudins are 20 to 27 kD proteins with 4 transmembrane domains that form two extracellular loops and whose N- and C-termini are localized on the cytoplasmic side of the plasma membrane. The C-terminal tail is long and is divergent between isoforms suggesting that anchorage to the cytoskeleton or scaffolding to signaling molecules may also be important in regulating claudin function.

Claudins were found to play an important role in determining the TER in MDCK1 and MDCK2 cells. Expression of claudin 1 in MDCK cells was found to increase the TER 4 to 5-fold over wild-type MDCK. Expression of claudin 2 in highly resistant MDCK1 cells, which normally express claudins 1 and 4, resulted in a decrease in TER and tight junction morphology similar to low-resistive MDCK2 that typically express claudin 2 in addition to claudin 1 and 4. This study demonstrated that strands containing different claudin isoforms are responsible for the variable barrier properties of different tight junction strands. Claudins have also been found to regulate ion selectivity. Indeed, expression of claudin 4 in MDCK will increase TER by decreasing Na^+ permeability without changing the permeability to Cl^-, the flux of mannitol, or the rank order of permeabilities of alkali metal cations. These studies all demonstrate that claudins are the proteins in the tight junction strand that are responsible for regulating the selective permeability of epithelial and endothelial cells.

How do different claudin isoforms create barriers with different selectivity? Although the mechanisms involved are not fully understood, current evidence supports the hypothesis that the specific structural characteristics of different claudin isoforms play a role in regulating the selectivity and barrier properties of TJs. Studies using expression of different claudin isoforms both singularly as well as in pairs have found that claudins can form mixed strands containing more than one isoform in each strand. In addition, claudins have been shown to bind in both a homophilic and a heterophilic manner. Heterotypic interactions only occur with specific pairs of claudin isoforms. For example, cells expressing claudin 1 or claudin 3 form tight junction strands when placed in mixed culture, whereas cells expressing claudin 2 will not form tight junction strands when mixed with either claudin 1-or claudin 3-expressing cells. It has been proposed that mixed strands containing claudin 1 and 3 would form a very restrictive barrier as these two isoforms bind to each other in a homotypic and heterotypic manner as shown (Fig. 14b). In contrast, a strand containing claudin 1 and claudin 2 would form a less restrictive barrier. In this strand, claudin 1 would bind to claudin 1 and claudin 2 would bind to claudin 2 in a homotypic manner, creating a barrier. However, at certain points in the strand, claudin 1 would oppose claudin 2 forming a pore that would allow the transport of molecules through the strand (Fig. 14b). As over 20 claudin isoforms have been identified, a number of different pairings could exist, allowing for different barrier properties in specific tissues.

Since the discovery of claudin, a number of inherited human diseases have been

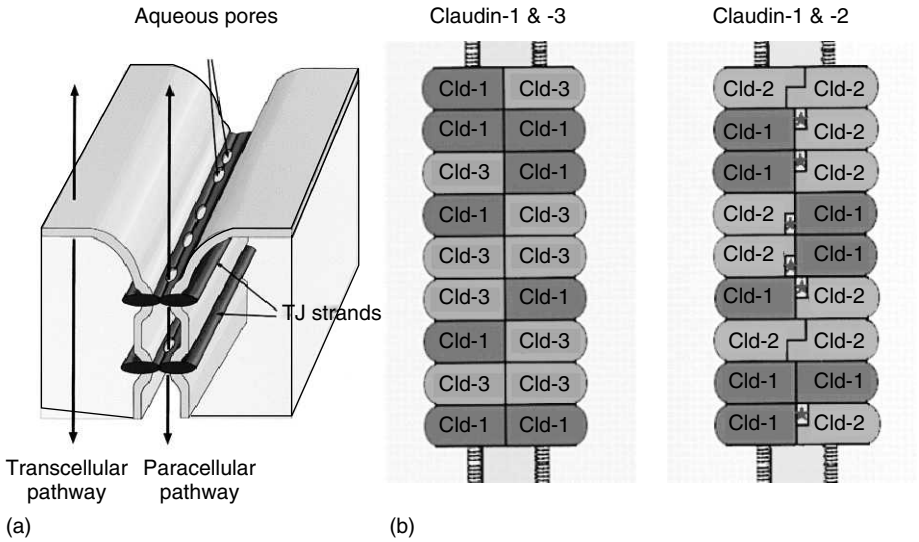

Fig. 14 Schematic of proposed model for paracellular transport through tight junction. A(a) The claudins are believed to form a strand containing aqueous pores that acts as a selective barrier to the flux of molecules between cells termed paracellular transport. (Bb) Schematic showing how claudins may interact to form a selective barrier. (See text for details). (Reprinted with permission from Tsukita, S., Furuse, M. (2000) Pores in the wall: Claudins constitute tight junction strands containing aqueous pores, *J. Cell Biol.* **149**, 13–16; Tsukita S., Furuse, M. 2000, *J. Cell Biol.*, **149**, 13–15).

identified for which mutations in specific claudin isoforms were demonstrated to be the cause of the underlying pathophysiology of the disease. Indeed, mutations in claudin 16 (paracellin-1) were identified in patients with renal hypomagnesemia, a rare disease characterized by a massive urinary loss of magnesium. Claudin 16 is expressed in the thick ascending limb in the kidney, a primary site of magnesium uptake. The current thought is that claudin 16 creates a channel that is selective for magnesium. This channel would be absent in patients with claudin 16 mutations; thus, magnesium would remain in the tubule and be lost in the urine. Mutations in claudin 14 have been shown to be responsible for nonsyndromic recessive deafness. Claudin 14 is located in the sensory epithelium in the organ of Corti, although its exact function in the inner ear is not completely understood. Knockout animals also provide evidence that claudins are responsible for the formation of highly selective and tissue-specific channels in tight junction strands. Claudin 5 is a major tight junction protein in endothelial cells with the greatest expression being found in the brain vasculature. Claudin 5-null mice were found to have normal vascular development and showed no change in the vascular barrier as assessed by the lack of edema during development. However, the transport of small molecules (<800 Da) was selectively increased in endothelial cells of the blood-brain barrier resulting in death 10 h after birth. Interestingly, mice lacking claudin 1 die shortly after birth due to dehydration that is the result of water loss across the epidermal

barrier of the skin. Importantly, removal of one claudin isoform does not result in the complete loss of tight junction strands in the affected tissue, thereby demonstrating that it is the combined function of different claudin isoforms that creates the selectivity of the tight junction.

Two other transmembrane components have been found to play a major role in the formation and regulation of TJs, occludin and junctional adhesion molecule (JAM). Occludin was the first protein to be isolated from tight junction enriched fractions. Immunofluorescent and immunoelectron microscopic analysis showed that this protein was localized to the tight junction strand. Like claudins, occludins contain four transmembrane regions with two extracellular loops, and their amino and carboxyterminal tails are located in the cytoplasm. Initial studies found that overexpression of occludin in MDCK cells would increase the number of tight junction strands and elevate TER. However, by generating occludin-deficient embryonic stem cells and occludin-knockout mice, it was shown that functional tight junction strands could be formed in the absence of occludin. Histological examination of certain tissues did show some abnormalities such as chronic inflammation and hyperplasia of the gastric epithelium, suggesting that occludin plays a regulatory role rather than establishing the barrier itself. This is supported by studies that have correlated changes in occludin phosphorylation with changes in barrier function. JAM is a single membrane-spanning protein with two IgG-like domains in its extracellular region that mediate homotypic binding. JAM is not integrated into the tight junction strand; however, studies have shown that JAM is involved in tight junction formation and barrier function possibly through an interaction with occludin.

2.5.2 **Plaque Proteins of Tight Junctions**

Like desmosomes and AJs, TJs also have a cytoplasmic plaque region containing proteins that serve both structural and signaling roles (Table 7). The plaque region of the tight junction is made up of a large number of proteins containing PDZ domains, named from the first three proteins first identified within this domain [PSD-95-postsynaptic density protein 95; Dlg-discs large proteinan; Zonula (ZO) occludins-1]. The PDZ domain mediates interaction with other proteins, including other PDZ proteins or transmembrane proteins containing the S/T-X-V in their C-terminus. As seen in Table 7, the PDZ containing proteins found in the tight junction can be divided into two subsets based on whether the protein contains a guanylate kinase homology region. Proteins containing the membrane-associated

guanylate kinase (MAGUK) also contain three to five PDZ domains and an SH3 domain. Of these proteins, the most closely studied group is the zonula occluding proteins (ZO-1, ZO-2, ZO-3). The zonula occluding proteins all bind to the claudins via their PDZ domains and can attach to actin filaments, thereby anchoring the tight junction to the actin cytoskeleton. ZO-1 and ZO-2 have also been found in AJs, presumably due to their ability to bind to α-catenin; however, their presence in the AJ may only occur in the absence of TJs. In addition, these proteins serve a scaffolding, role localizing transcription factors and signaling proteins to the tight junction plaque. For example, ZONAB (ZO-1-associated nucleic acid binding protein) is a transcription factor that acts as a repressor of Erb-2 promoter. ZONAB function is regulated, in part, by the sequestration of ZONAB at TJs through its binding to ZO-1.

Attachment to the actin cytoskeleton has been implicated as a possible control point for the regulation of tight junction function. A number of proteins located in the tight junction plaque can directly link claudin to the actin cytoskeleton as described for ZO proteins. Interestingly, occludin has been found to directly link to actin filaments. The tight junction may also serve as a site regulating cytoskeletal dynamics. Indeed, myosin II is localized to the tight junction plaque through its association with cingulin. The structure of cingulin contains a globular N-terminus linked to a coiled–coiled domain that allows for the formation of dimers. The N-terminus mediates binding to ZO-1, ZO-2, JAM, and actin. The C-terminus has been shown to bind nonmuscle myosin II. Other proteins that act to bundle actin filaments, such as cortactin, are also localized to the tight junction plaque. Although it is clear that the tight junction is associated with the actin cytoskeleton, the functional significance of this attachment is not clear. Studies have attempted to disrupt actin interaction through the expression of mutant proteins; however, these studies are hampered by the endogenous levels of these proteins and/or by the ability of other proteins to compensate for the lost protein function. A major area for future research will be to determine how the interaction of the plaque proteins with the actin cytoskeleton regulates *de novo* assembly, reorganization, and acute regulation of the paracellular permeability of the tight junction.

2.5.3 Regulation of Tight Junction Assembly/Disassembly

The close association between tight junction function and the actin cytoskeleton implicates the small GTPases (Rho, Rac, and Cdc42) in the regulation of the barrier function of tight junctions. A number of studies have used the expression of dominant negative or constitutively active forms of these proteins and found that the expression of either form decreases TER, increases paracellular soluble flux, and decreases fence function. These findings suggest that the activity of Rho GTPases needs to be tightly regulated, as either increased or decreased activity will disrupt tight junction function. Alternatively, localized activation of GTPase activity may be an important factor in regulating changes in TJ function. Local changes in activity could be controlled by guanine nuclear exchange factors (GEFs) associated with the tight junction plaque proteins. GEF-H1/Lfc has recently been found to localize in the TJ and overexpression of wild-type GEF-H1/Lfc increased

paracellular permeability to 4-kDa dextran, whereas depletion of this GEF by siRNA decreased the permeability. Interestingly, changes in the level of GEF-H1/Lfc did not change TER or the permeability of higher molecular weight molecules. In addition, no change in the morphology of the tight junction was noted, suggesting that local activation of Rho produces only subtle changes in tight junction activity. Identification of other GEFs and GAPs associated with the tight junction along with identification of signaling pathways that activate these molecules will be important for elucidating the role of small GTPases in the regulation of tight junctions.

As is the case with AJ proteins, the plaque proteins found in tight junctions are also phosphorylated on serine, threonine, and tyrosine. Occludin, ZO-1 and ZO-2 have all been found to be phosphorylated on all three residues under various experimental conditions; however, no clear association between phosphorylation of these proteins and TJ assembly and/or function has been firmly established. A number of kinases have been identified as residing in the tight junction complex including occludin-associated kinase, ZO-1-associated kinase, and several PKC isoforms. Of the PKC isoforms localized to the TJs, only the atypical PKCs (aPKCs) have been shown to play a definitive role in junction assembly. The aPKCs have been shown to form a complex with PAR3 (also known as ASIP, a PKC-specific interacting protein), PAR6, and two PDZ proteins that are found in the tight junction complex. A number of studies support a role for aPKC/PAR3/PAR6 in the formation of the tight junction. For example, expression of kinase-deficient aPKC was found to prevent the reforming of tight junction in the Ca^{++} switch assay. In addition, the expression of wild-type PAR3 has also been shown to increase the rate of tight junction formation. Phosphorylation of PAR on Ser827 by aPKC was shown to decrease aPKC binding to PAR3 and increase junction formation. PAR6 was found to complex with PAR3 and aPKC and to link this complex with Cdc42, which, as explained in the following section, may play an important role in tight junction formation.

The formation of AJs has been demonstrated to trigger the formation of TJs. Although the exact order of arrival for the components of AJs and TJs is not known, the following model was proposed. Initial contact between two epithelial cells has been shown to occur when the tip of a filopodia from one cell contacts an adjacent cell. This allows E-cadherin and nectin to form microclusters at this relatively small point of cell–cell contact. The cadherin in this cluster begins to recruit α-catenin, while the nectins recruit afadin, resulting in the association of this microcluster with the actin cytoskeleton. The junction expands as actin polymerization is stimulated through activation of Rac and possibly through recruitment of Arp 2/3 by E-cadherin and nectin transdimerization. Nectin has also been shown to activate Cdc42, which, in conjunction with Rac, will also stimulate actin polymerization, thereby increasing junction stability. In addition, Cdc42 also activates aPKC resulting in the phosphorylation of PAR3. PAR3 can associate with JAM, which is recruited to the apical side of the AJ. JAM and PAR3 and possibly ZO-1, which can associate with α-catenin, may then serve as an assembly site for the tight junction, which matures into a distinct junction complex as shown in Fig. 15. The knockdown of specific

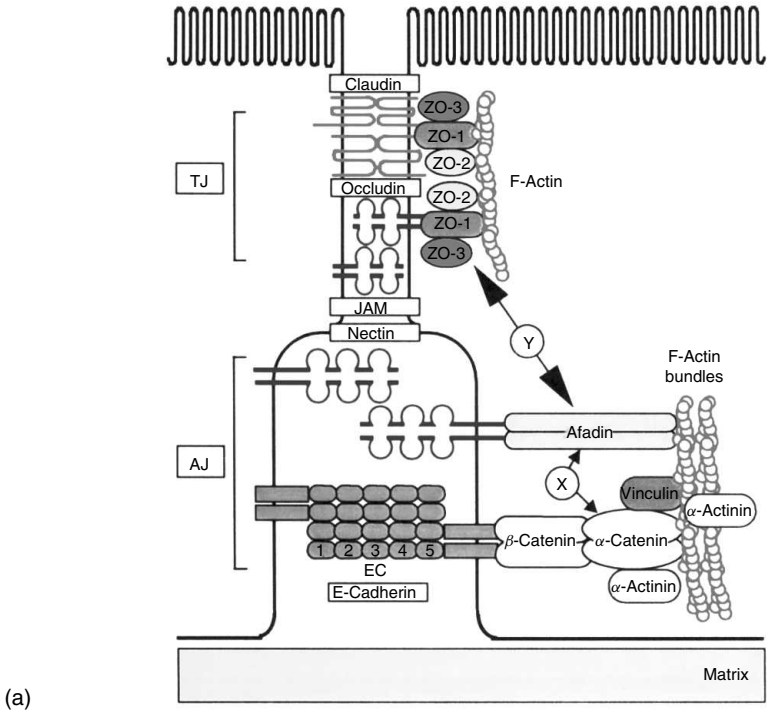

Fig. 15 Model for the formation of adherens and TJs. (a) Multiple proteins are localized to mature adherens and TJs. Some proteins such as ZO-1 can be found in both types of junctions and have been proposed to serve as intermediates allowing AJs to initiate tight junction formation. (b) Filopodia from one cell contact an adjacent cell allowing cadherins and nectins to cluster. As the cadherin/nectin junction expands JAM is incorporated, resulting in the localization of tight junction proteins and the initiation of tight junction formation. The tight junction matures into a separate structure. (Reprinted with permission from Takai, Y., Nakanishi, H. (2003) Nectin and afadin: novel organizers of intercellular junctions, *J. Cell Sci.* **116**, 17–27).

proteins in this proposed model using techniques such as siRNA (small interfering RNAs) will be critical in determining the importance of the AJ to tight junction assembly.

3 Summary and Future Directions

The interaction of cells with the ECM and withone another plays an essential

role in most if not all physiological processes. Much is already known about the mechanisms regulating cell–matrix and cell–cell adhesion. Important components of cell junctions and their signaling pathways have been identified and characterized. Current evidence suggests that there are many different junctional-binding proteins providing alternative cytoskeletal linkages and signaling pathways to mediate cell function. A challenge for the future will be to determine the significance of individual linkages and pathways in diverse physiological contexts. Additionally, most of what we know about cell junctions has been gained from two-dimensional (2D) cell culture models focusing on specific protein–protein interactions. Although these studies have provided important insights into the mechanisms regulating the functions of specific proteins, a future task will be to determine the role of these mechanisms in complex biological systems. Gene knockout studies have provided an important starting point. However, cell adhesion and signaling proteins have multiple interaction partners. Thus, more information will be gained from future ''knockin'' studies of these proteins with mutations that inhibit individual aspects of protein function.

Additionally, the view of cell–matrix and cell–cell adhesions as sites of mechanotransduction is growing in momentum. Multiple examples are available to demonstrate the activation of integrin signaling by changes in hemodynamic shear stress on endothelial cells. Additionally, it has been known for many years that the response of cells to their ECM environment not only depends on specific integrin–ligand integrations but also on the physical state of these ECM ligands. The rigidity of the ECM can dramatically affect cell behavior. Changes in ECM rigidity have been modeled experimentally using three-dimensional collagen matrices. Rigid collagen matrices that are attached to a culture provide resistance to cell-generated contractile forces at cell–matrix junctions, whereas nonrigid collagen matrices that float in culture medium do not. Interestingly, mammary epithelial cells differentiate into aveolar-like structures containing basement membranes, and secrete milk proteins when cultured in nonrigid three-dimensional collagen matrices. However, mammary cells fail to differentiate and continue proliferating when cultured in rigid three-dimensional matrices. In contrast, the differentiation of fibroblasts into myofibroblasts requires the increase in ECM rigidity that accompanies wound healing. In culture, fibroblasts differentiate into myofibroblasts when cultured in rigid, but not in nonrigid, three-dimensional collagen matrices. Clearly, identifying the molecular mechanisms that govern mechanotransduction at cell junctions is an important area for future investigation.

Finally, in most instances, integrins and cadherins regulate cell behavior by collaborating with other cell surface receptors. For example, the interaction of VE-cadherin with VEGF-receptor 2 modulates VEGF-induced signaling, perhaps by clustering the VEGF receptor with phosphatases in the AJ. In addition, evidence suggests that E-cadherin may cocluster and activate the EGF receptor resulting in activation of EGF signaling independent of the EGF ligand. Similar observations have been made in studies examining the collaboration between integrin and growth factor receptor signaling. Thus, the molecular mechanisms governing the cross-talk between cell junction proteins and other signaling receptors will be a continuing area of intense investigation.

Keywords

Chromosome
The structural unit of genetic material.

Nuclear Architecture
Nuclear structures that influence nuclear function.

Nuclear Matrix
Protein network throughout the nucleus.

Gene Expression
Genes are decoded into RNA, which is translated into protein.

DNA Replication
DNA is copied by enzymes into 2 identical molecules.

DNA Repair
DNA damage is corrected to maintain genetic integrity.

Cell Cycle
Sequence of events that yields 2 daughter cells from a single mother cell.

The nucleus is an organelle that is found in eukaryotes but not in prokaryotes. Nuclei contain the genetic information that defines the appearance and behaviour of an organism. The genetic material - DNA - is packaged as a DNA-protein complex, called chromatin, into units of manageable size, called chromosomes. In multicellular eukaryotes, different types of cells are defined by the different genes that they express. Patterns of gene expression arise during cell differentiation and reflect a cells position in the organism during development. Gene expression is regulated at many levels in each cell. The major regulatory step occurs during transcription, when the gene is copied by transcription into messenger RNA. Messenger RNAs transfer genetic information to the cytoplasm and provide the template for protein synthesis during translation. Higher eukaryotes contain very large numbers of cells that are derived from a single precursor - a fertilised egg. The genetic material of this cell is derived from the egg and sperm of the female and male parents. During development, cells must perform many cycles of DNA duplication and cell proliferation. The genetic information must be faithfully copied during DNA replication and any damaged corrected by DNA repair, so that the same genetic information is passed to all cells of the organism. This chapter describes these fundamental biological processes and explains how they are regulated within the nucleus of eukaryotic cells.

1 Introduction

Eukaryotes are defined by the presence of a nucleus in their cells. In most eukaryotes, the nucleus is the most prominent organelle. It is the cellular compartment where the vast majority of genetic information is held (mitochondria and chloroplasts contain very small DNA molecules). The genetic code is held within the DNA. Each human cell has roughly 6×10^9 bp DNA. This is far too much to be held in a single molecule within the cell, as in bacteria, so the DNA is divided between a number of

chromosomes. Somatic human cells are diploid and a vast majority have the same genetic information, which is held within the 46 chromosomes – 22 pairs of autosomes called chromosomes 1–22 and 1 pair of sex chromosomes, XX in females or XY in males. This DNA is folded as chromatin to form chromosomes and it is this DNA–protein complex that serves as the genetic substrate that supports the major functions performed by DNA. The major functions are as follows:

1. DNA synthesis – called *DNA replication* – ensures that the same genetic complement is passed from the fertilized egg to all subsequent cell descendants.
2. RNA synthesis – called *RNA transcription* – ensures that genes are expressed in the appropriate cells at the required times throughout the development of an organism. Different patterns of gene expression in different types of cells and tissues are determined by patterns of differentiation.
3. DNA repair ensures that the integrity of genetic information is maintained so that the same DNA sequence is found in all cells of the body. Defects in DNA repair can lead to a variety of diseases through sporadic mutations, and are particularly important during the development of cancer.

Different aspects of chromatin function and nuclear structure are fundamental to the development of multicellular organisms. The nucleus itself plays a vital role in this development by ensuring that functions performed on chromatin are isolated from major cytoplasmic activities such as protein synthesis and energy metabolism. This separation inevitably demands that a critical step of the gene expression process involves the transfer of information from each gene to the cytoplasm where it can be decoded to generate the corresponding protein. The genetic intermediary involved is called *messenger RNA* (mRNA) and the process of protein synthesis is called *protein translation*. The fact that eukaryotic cells are divided into two major compartments by the nuclear membrane has a number of implications. One disadvantage is the need to develop complex systems to regulate compartmentalization and control traffic between the two compartments. The major advantage is that separating protein synthesis from the compartment in which DNA function is performed allows quality controls to be installed to ensure that protein synthesis is only performed on intact and authentic mRNAs. In bacteria, transcription, translation, protein folding, and incorporation of the nascent folding polypeptide into the functional sites are coupled, so that in principle the nascent protein might still be attached – through the ribosome, mRNA and RNA polymerase – to its gene. In eukaryotes, much more complex gene structures, and in particular, the fact that most genes contain intervening sequences that do not hold protein coding information, demands that the events of mRNA and protein synthesis are uncoupled.

2 Nuclear Function

The basic molecular mechanisms that dictate most aspects of nuclear function are known in detail and it is only appropriate to cover the fundamental principles here.

2.1 Gene Expression

Eukaryotic gene expression follows the general principles developed during the evolution of prokaryotes. Put simply, gene expression is dictated by DNA sequences within gene promoters that determine how the RNA synthetic machinery, RNA polymerase, is positioned on the gene. In multicellular eukaryotes, highly complex patterns of gene expression have evolved and correspondingly complex mechanisms of gene regulation are seen. Nevertheless, the same basic principle underlies the activation of RNA synthesis.

In contrast to prokaryotes, which have a single RNA polymerase, three different RNA polymerase complexes perform RNA synthesis in eukaryotic cells. In most mammalian cells, RNA polymerase II (pol II) is the major activity, transcribing all protein-coding genes to generate patterns of gene expression that determine cell type; humans have about 250 distinct cell types. Synthesis is performed by an ~4 MDa holoenzyme containing the pol II core enzyme and other activities required during RNA synthesis and processing. RNA polymerase I (pol I) is dedicated to the synthesis of the repeated ribosomal RNA (rRNA) genes, within specialized nuclear sites – nucleoli – and RNA polymerase III (pol III), a minor nucleoplasmic activity, transcribes transfer RNA (tRNA) and 5S rRNA genes. Small nuclear RNA (snRNA) and small nucleolar RNA (snoRNA) genes encode structural RNAs needed for RNA processing; some are transcribed by pol II and others by pol III.

A proliferating mammalian cell supports a continuous rate of RNA synthesis of $\sim 2 \times 10^8$ nucleotides min^{-1}. This will be roughly 40% pre-rRNA, 60% pre-mRNA (hnRNA) and only 2 to 3% 4 to 5S RNA (5S and pre-tRNA). Synthetic rates are 3 to 4 kbp min^{-1} for pol I and 1.5 to 2 kbp min^{-1} for pol II/III respectively and average transcript lengths of ~13.5, ~15 and ~0.1 kb for pol I, pol II, and pol III. These values correspond to ~20 000, ~60 000 and ~3000 engaged pol I, II, and III complexes per cell. It is also important to consider the density of pol complexes on individual genes. A chromatin spreading technique called *Miller spreads* can be used to show that the active rRNA genes of mammalian cells each support 100 to 120 pol I complexes. In sharp contrast, pol II transcription units generally support very few widely dispersed active complexes. Even when studying adenovirus at the time of the highest viral transcription, the active genomes have only four (on average) associated transcription complexes.

Most tissues of mammalian origin express at least 10 000 genes. In rat liver, for example, there are ~10 species present at ~10 000 copies per cell, 500 at ~200 copies per cell and ~10 000 at ~10 copies per cell (33) – ~300 000 mRNAs per cell, in all. Note that even after accounting for mRNA turnover, it is clear that the majority of genes generate so few transcripts that they must be transcriptionally inert for most of the time. In addition, it is interesting that many pol II complexes seem to be involved in synthesis that generates RNA molecules that turnover in the nucleus. Many of these are intergenic transcripts that have been speculated to play a role in maintaining an active chromatin status across extended gene domains.

2.1.1 Activating Gene Expression

The critical feature of gene expression in eukaryotes is that the transcription machinery is recruited to genes through its interaction with transcription factors and

adaptor proteins that interact with these factors. Genetic elements within the gene promoters define where the transcription will begin. General transcription factors play a fundamental role in this process. For most eukaryotic promoters, the process is activated by association of the factor TFIID with DNA. TFIID is a large multiprotein complex, one subunit of which, the TATA sequence binding protein (TBP), can recognize and associate with the canonical promoter element TATA. TFIID bound to the promoter can then activate the sequential recruitment of other factors as follows: TFIIB; TFIIE with TFIIF and RNA polymerase; TFIIH. Once assembly of this preinitiation complex is complete, the TFIIH complex directs phosphorylation of a domain of the RNA polymerase complex called the *C-terminal domain* (CTD). The CTD is conserved in eukaryotic RNA polymerase II proteins. The mammalian enzyme has 52 repeats of the amino acid (consensus) sequence YSPTSPS, in which the serine (S) and threonine (T) residues can be phosphorylated. Phosphorylation of the CTD correlates with release of the synthetic complex from the promoter and the initiation of RNA synthesis. During synthesis, the DNA template is used to generate a corresponding RNA molecule, which is polymerized from its 5′ toward its 3′ end. The 3′ end of the transcript is generated by a process that cuts the nascent RNA and adds a poly(A) tail. This process recognizes a set of sequence elements in the RNA that interact with the poly(A) synthesis machinery. Once the nascent RNA is processed in this way, the engaged polymerase complex is destabilized so that it will soon dissociate from the template – this termination step appears not to be directed by a specific sequence in DNA and is thought to be more probabilistic, so that the polymerase ''drops off'' the DNA at some point within a few kbp at the end of the gene.

2.1.2 Specific Transcription Factors

The general transcription factors provide only part of the mechanism that regulates gene expression in higher eukaryotes. In multicellular organisms, it is clear that complex mechanisms of regulation are required to ensure that particular genes are expressed in the desired cells and at the appropriate times of development. This function is performed by specific transcription factors. As the name implies, specific transcription factors function to activate transcription from a single gene or a group of genes with similar expression characteristics. As a general rule, genes that are expressed in a specific cell lineage will only be expressed in cells with the appropriate constellation of transcription factors. Certain specific transcription factors will play a dominant role in maintaining the active chromatin status across target genes. Others will activate or enhance levels of gene expression beyond the levels that are provided by the general transcription factors alone.

It is self-evident that this class of transcription factors must achieve specificity by virtue of their interaction with specific DNA elements within target genes. For most factors, the DNA target will lie within 1 to 2 turns of the double helix. These DNA elements can be located close to the promoter itself, within promoter proximal activating sequences, but, in many cases, these are located in transcriptional enhancer elements that can be as much as 100 kbp for the gene promoter. This surprising observation reflects the fact that the chromatin itself is flexible and able to fold, so that the remote sequences and associated factors can contribute to the efficiency with which gene expression is

activated at the corresponding promoter. An excellent example of this is provided by enhancer elements within the mammalian β-globin locus control region (LCR), which are located about 50 kbp from the gene promoters in this locus that are activated at different times of development.

Particular features of the transcription factor proteins generate binding specificity. Many classes of transcription factor have been described, but the majority of factors fall into three main groups with (1) helix–turn–helix motifs; (2) zinc fingers; (3) leucine zippers.

The homeodomain of vertebrate hox genes is a classical example of the helix–turn-helix transcription factor motif. The homeodomain is composed of 60 amino acids that fold as three helices. Helices 2 and 3 form the helix–turn–helix motif and helix 3 interacts with the major groove of DNA.

Though variants have been described, the characteristic feature of the zinc finger motif is a zinc atom associated with two cysteine and two histidine residues. The human Gli protein is a good example that is involved in bone development and also amplified in some human tumors. The factor contains five zinc fingers, of which four interacts with each of the major grooves of DNA where they wrap around the DNA for a full helical turn. Extensive contacts between the amino acids of these structures and the bases and phosphate residues in DNA together generate specificity of factor binding.

The human oncogenes *Fos* and *Jun* are members of the family of transcription factors that bind to AP-1 sites within promoters. *Fos* and *Jun* are able to form heterodimers by virtue of the precise spacing of hydrophobic leucine residues in the domains of the two monomers that provide a surface for interaction – the leucine zipper. The alpha helices within the monomers ''zip'' together to create a coiled coil and a proximal basic region that is generated in the dimer to provide a DNA-binding domain. This basic region has two lysine/arginine-rich regions separated by an invariant asparagine that together generate an interaction with the major groove of the DNA.

2.1.3 Posttranscriptional Events – RNA Processing

In eukaryotes, the primary transcripts of protein coding genes must be processed before the mature messenger RNAs (mRNAs) are able to pass to the cytoplasm. The processing steps include the following:

1. Addition of a 5′ cap structure – this occurs cotranscriptionally and serves a role in RNA structure and stability. Formation of the RNA cap involves the addition of 7-methyl guanylic acid to the 5′ triphosphate of the nascent transcript, in a reaction that involves the two triphosphate moieties. During this three-step reaction, the γ-phosphate of the RNA is first removed by RNA triphosphatase, GTP-RNA guanyltransferase then adds GMP to the new terminal and finally the methyl group is added by RNA-guanine-7-methyltransferase. The cap may be further modified by the addition of 2–O-methyl groups to the first or first and second ribose residues of the transcript.
2. The protein coding sequences of many eukaryotic genes are interspersed with noncoding introns, which must be removed in order to generate mature mRNA. This process, called *RNA splicing*, begins at the time of transcription and is completed posttranscriptionally, at the transcription site. Splicing is

catalyzed by a number of small nuclear RNA-protein complexes (snRNPs). The RNAs involved are called U1, U2, U4, U5, and U6 (U3 is involved in rRNA processing). U1 snRNP binds to the 5′ splice site and U2 snRNP the intronic branch acceptor site. A U4/U6.U5 complex then assembles so that U6 snRNP replaces U1 at the 5′ splice site. U2 and U6 RNAs then pair to form the catalytic site and U5 pairs with the end of the 5'exon. Splicing proceeds through two transesterification reactions that form first a lariat at the internal acceptor site and finally the spliced product. Many proteins – such as the SR proteins (see 3.5.4) – are involved in this splicing reaction and one consequence of the splicing process is the formation of a mature RNA–protein complex that is required for mRNA export to the cytoplasm.

3. The 3′ end of the mRNA is generated by a processing event that adds a poly(A) tail (typically of 150–200 residues) to the nascent transcript. This serves a structural role and is important for RNA stability. Two elements within RNA determine the location of the poly(A) tail. The polyadenylation signal, AAUAAA, binds the cleavage poly(A) specificity factor (CPSF) protein and a downstream element, UGUGUG, binds the cleavage stimulatory factor (CstF). These two proteins interact with and position the cleavage factor proteins (CFI and CFII) and poly(A) polymerase (PAP), which together generate cleaved RNA with a poly(A) tail.

2.2 DNA Replication

The vast majority of cells in multicellular eukaryotes contain the same genetic information that is descended from an original diploid cell – the fertilized egg. It is self-evident, that if cells are to maintain their genetic integrity the proliferation process must be tightly controlled so that cell division can only proceed once the genetic material – DNA – of the mother cell is fully duplicated. This process of DNA replication is clearly central to the activities of cell proliferation and is the target for a wide variety of cellular controls and checkpoints (quality controls).

Prokaryotes such as the bacterium *Escherichia coli* have a circular genome and initiate DNA synthesis at a single site, the replication origin, *OriC*. The molecular details of this process are known. Quite clearly, the size and complexity of eukaryotic genomes demand that many more initiation events occur. In human cells, origins of DNA replication are about 150 kbp apart, which means that an average chromosome will have ~1000. The molecular mechanisms that define replication origins involve the association of a protein complex with DNA. This complex includes a multi-subunit origin recognition complex (ORC1–6), and an MCM 2 to 7 complex that restricts initiation to one event/origin in each cell cycle, and proteins that are targets for the cell cycle machinery that activates the replication process. Once an origin is activated the synthetic machinery is recruited to the origin and replication ensues.

For most eukaryotes, it is not clear how the origins of DNA replication are defined. The yeast *Saccharomyces cerevisiae* is an exception. In this organism, replication origins can be defined as autonomous replicating sequence (ARS) elements that are about 200 bp in length and have consensus sequence motifs – called *the A and B elements* – that act as DNA unwinding

elements and serve as target sites for the recruitment of ORC. No equivalent sequences have been defined in multicellular eukaryotes and it is believed that origins are defined by a complex combination of genetic and epigenetic features.

Duplication of the DNA double helix proceeds by a semiconservative mechanism. The DNA duplex is first opened to separate the two strands, each of which then serves as a template to generate two identical daughter DNA molecules. The synthetic enzymes responsible for the synthetic process are called *DNA polymerases* (Table 1). Many other proteins are involved in the replication process (Fig. 1). The critical first step of the replication process, DNA denaturation is driven by an enzyme called *DNA helicase*. Helicases unwind the DNA template. The newly formed single-stranded regions are stabilized by a DNA-binding protein called *replication factor-A* (*RF-A*). The DNA replication then begins. However, DNA polymerases are unable to initiate the synthetic process-initiation requires that a DNA dependent RNA polymerase called *a primase*, first generates short (usually about 5 bp) RNA primers at each replication origin. DNA polymerase-α then proceeds to synthesize DNA by extending the RNA primer. DNA polymerase-α is not especially processive (i.e. efficient at copying long stretches of DNA) and soon after initiation the synthetic process is assumed by DNA polymerases-δ and/or -ε.

The antiparallel structure of DNA adds a certain complexity to the replication process. Because of the reaction mechanisms that drive chain elongation, the polymerization process can take place only in one direction – nucleic acids only grow from the 5′ to 3′ ends. Replication from a single origin almost always occurs in two directions, so that each origin will have four associated polymerase complexes, two at each growing replication fork (Fig. 1 shows the proteins at one of the two forks). At each fork, replication of one

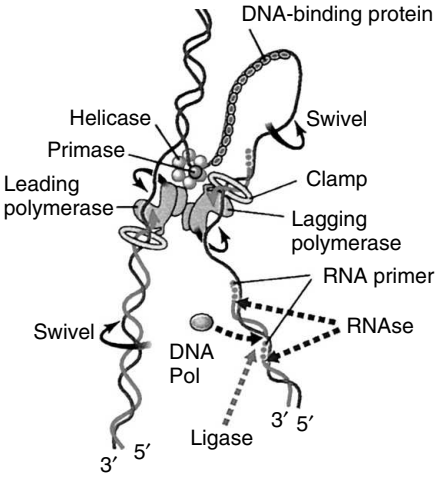

Fig. 1 Replication proteins of a single replication fork. Two replication complexes are required to replicate each replication fork. The activity of the two complexes is coordinated in the cell – they are thought to be associated as shown here. The requirement for leading and lagging strand synthesis is described in the text. In mammalian cells, the DNA clamp, which holds the polymerase complex on DNA is a trimer of PCNA (proliferating cell nuclear antigen) and the primer that is needed to activate DNA synthesis is a component of DNA polymerase-α. DNA synthesis is performed by the combined activities of DNA polymerases-α, -δ, and -ε. The swivel that is required to release superhelical stress that develops during elongation is provided by topoisomerases I and II. (Reproduced from von Hippel, P.H., Jing, D.H. (2000) Structural biology – Bit players in the trombone orchestra, *Science* **287**, 2435–2436 and adapted from Yuzhakov, A., Kelman, Z., O'Donnell, M. (1999) Trading places on DNA – A three-point switch underlies primer handoff from primase to the replicative DNA polymerase, *Cell* **96**, 153–163. With permission of American Association for the Advancement of Science and Cell Press.)

strand can occur continuously in the 5′ to 3′ direction. This is called the *leading strand synthesis*. On the other strand, called the *lagging strand*, replication occurs only when a single-stranded patch of about 200 bp has formed. Synthesis then proceeds to fill the patch, so that the replication products on the lagging strand are all initially short, in mammalian cells typically 100 to 500 bp in length. These short fragments, called *Okazaki fragments*, are then ligated together – by an enzyme called *DNA ligase* – in a process that replaces the RNA primers with DNA and joins the gaps between adjacent Okazaki fragments. It is believed that the leading and lagging strand enzyme complexes are associated so that their activities can be readily coordinated (Fig. 1) and it has even been suggested that the complexes associated with the two forks arising from each origin are held together.

2.2.1 **DNA Repair**

The maintenance of genetic integrity demands that the DNA is duplicated faithfully from one cell generation to the next and that any damage that might arise in the DNA can be recognized and corrected. In mammalian cells, our best estimates suggest that the sequence of DNA changes at a rate of 1 bp/10^9 bp replicated during each division cycle. In fact, it is important that this level of accuracy is maintained, as most mutations in protein coding genes are likely to be deleterious. Repair is clearly extremely important. Xeroderma pigmentosum (NER), Blooms syndrome (ligase) and ataxia telangiectasia (ATM) are examples of diseases in which affected individuals have defective DNA repair pathways. These defects correlate with a massively increased risk of cancer.

In proliferating cells, a major potential source of DNA mutation is base misincorporation during the course of replication.

Errors are not uncommon, but very effective proofreading and postreplicative mismatch repair activities ensure that the genetic information encoded in the parental DNA strand is preserved during DNA replication.

In addition to this, numerous sources of DNA damage have the potential to generate lesions that will ultimately give rise to mutations in DNA (Table 2). Classes of DNA damage include the following:

1. Chemical or oxidative damage that might lead to base modification or base excision. For example, spontaneous hydrolysis can cause deamination (e.g. turning cytosine to uracil) and depurination (e.g. removing a guanine base).
2. Ultraviolet light induces a photochemical cyclization between adjacent thymine/thymine or thymine/cytosine residues.
3. Ultraviolet light and other types of radiation can induce single- and double-strand breaks in the DNA backbone.
4. Some chemicals can interact with the DNA to form bulky adducts or intercalate into the DNA. Both processes are potentially mutagenic.

Together these insults ensure that the DNA within each mammalian cell will experience many thousands of lesions every day. To cope with this, cells employ a variety of repair mechanisms (Table 2). In each case, the efficiency of the process relies on the fact that the structure of DNA provides a template for repair. The general mechanism of DNA repair involves three basic steps. The first involves the recognition of damage and excision of the damage by DNA repair nucleases. A DNA polymerase can then bind to the free 3′-OH end of the cut DNA and fill the gap using the complementary DNA strand as template. Finally, the nick that remains in the DNA backbone following incorporation of the new base(s) is sealed by the DNA ligase.

Depurination is the most common form of a potentially mutagenic lesion

Tab. 2 DNA repair mechanisms and damage types.

Mechanism	*Damage*	*Repair proteins involved*
Exonuclease of DNA polymerase	Inaccuracies during DNA replication (proofreading)	DNA pol δ/ε, ligase
Base-mismatch repair	Small adducts	MSH6/3-MSH2 (dimer)
	Insertions/deletions	PMS1, MLH1, PCNA
	Oxidative damage	DNA polδ, ligase
Nucleotide excision repair	Bulky adducts	XPA – XPG, RPA, TFIIH
	UV cross-links	ERCC1, DNApolδ/ε PCNA, ligase
Base excision repair	Abasic sites	N-glycosidases
	Deamination	AP endonuclease
	Oxidative damage	DNApolβ, DNA ligase
	Alkylations	
Homologous recombination	Strand breaks	RAD51, other RAD proteins RPA, DNApol, ligase p53, BRCA1, BRCA2
DNA end-joining	Strand breaks	Ku70, XRCC5, DNAPK p53, ATM

in DNA. In this case, the DNA with a missing base is recognized by the enzyme AP endonuclease, which then cuts the DNA phosphodiester backbone at the 5′ side of the altered site. The sugar and phosphate are then removed by a phosphodiesterase and DNA sequence restored by DNA polymerase-β and DNA ligase using the complementary DNA strand as template. Base excision repair provides an alternative repair pathway that involves a family of DNA glycosylases. These enzymes recognize altered bases in DNA and catalyze their removal so that the natural DNA sequence can be restored.

Nucleotide excision repair provides a quite different repair pathway that is capable of repairing many types of DNA that distort the structure of DNA. Typical example of damage that is removed by this pathway include the thymine dimers and 6 to 4 photoproducts (C-T dimers) caused by ultraviolet irradiation (sunlight) and ''bulky adducts'' such as those created by the covalent reaction of DNA with hydrocarbons like the carcinogen benzopyrene. In this case, a large multienzyme complex scans DNA for damage and on recognition uses nucleases to remove a DNA patch of about 30 bp. Helicase activity (XPD) is required to remove the DNA strand containing the damage and this is then repaired by DNA polymerase and ligase using the complementary DNA strand as template. The process also involves the transcription factor TFIIH. This is recruited to the repair site and concomitantly leads to a downregulation of RNA synthesis, which prevents the cell from attempting transcription of damaged DNA.

The importance of preserving the genome intact cannot be overstated as many classes of lesion can be mutagenic and will ultimately lead to cancer. Robust pathways are in place that minimize the likelihood of damage leading to cancer. For example, both ionizing and ultraviolet radiation induce the activity of protein kinases such as the mammalian ATM protein, which alters the phosphorylation status of the protein p53; p53 has been termed *the guardian of the genome*. This enhances the stability of p53 by reducing its interaction with the inhibitor of p53 function called MDM2 and stimulates the transcription factor activities of p53, increasing the synthesis of p21, an inhibitor of cell cycle progression, and the proapoptotic protein BAX. If DNA damage is sufficiently severe, the cell is committed to die. The combined activities of ATM, ATR, chk1, and chk2 also serve to ensure that DNA synthesis is downregulated, to reduce the possibility that replication might proceed through damaged regions of the genome and so fix mutations into DNA.

2.3 The Cell Division Cycle

Multicellular organisms must continuously replace cells that are damaged or have otherwise fulfilled their natural purpose. Cell replacement operates through a proliferative ''cell cycle'' during which mitogenic cues (growth factors) from the local environment activate a complex series of events that will ultimately lead each parental or mother cell to divide into two genetically identical daughters. The cell cycle should be viewed as a continuous process, though for descriptive simplicity it is usually broken down into four phases – G1, S, G2, and mitosis. Mitosis is by far the most visibly distinct phase, which can be watched in living cells using a simple optical microscope. Mitosis might be viewed as the culmination of the

cycle as it incorporates the dramatic structural changes that are required to generate the daughter cells. Mitosis can only occur if the chromosomes within the mother cell are first duplicated. This is the most critical requirement of the proliferation process and eukaryotes have developed a number of quality control mechanisms called *checkpoints* to ensure that growing cells can only attempt mitosis once the process of DNA duplication is complete. Other mechanisms ensure that the initiation of replication is tightly regulated so that chromosomes are replicated once, and only once in each cycle. The process of DNA synthesis takes place in the S-phase (for synthesis phase) of the cell cycle. G1 and G2 are gap phases that separate the distinct S- and M-phases. During these phases – and also during S-phase – the cell grows and so continuously assimilates and accumulates the components that are required to generate two new cells at the end of mitosis. It goes without saying that if proliferating cells are to maintain the required structural characteristic, each cell that forms during mitosis must double in mass before the next mitosis takes place.

For mammalian cells, a typical cell cycle will be completed in about 24 h. Breaking down as: G1 6 to 10 h; S 8 to 10 h; G2 3 to 5 h; M 1 h. Variations in cell cycle occur predominantly during G1. The major cues for proliferation are driven by families of cell cycle proteins called *cyclins* and cyclin dependent kinases (cdks or cdcs). The critical step that commits a cell to proliferation occurs late in G1, about 2 h prior to the onset of S-phase. This position of the cell cycle is referred to as ''start'' and once a cell passes this point it is locked into a cycle of events that will inevitably lead to the formation of the daughter cells. A critical part of this transition involves the phosphorylation of the tumor suppressor protein Rb (retinoblastoma protein) by a cyclinD/cdk4/6 and cyclinE/cdk2 complexes (Fig. 2). This Rb modification alters the association of Rb with a family of transcription factors – E2F1–6 and DP1–2 – that function to activate the expression of other genes involved in the cell cycle progression and DNA replication, such as cdc2 and DNA polymerase 2. The activity of the cyclin/cdk complexes is driven by mitogenic cues and restrained by the tumor suppressor proteins $p21^{cip/kip}$ and $p16^{INK4a}$.

Cells with protracted cell cycle times have extended pre-start periods. In addition to this, cells with proliferative potential can ''rest'' in a G0 phase of the cycle. This state is usually perceived as an extension of the G1 phase where cells are able to respond to growth signals once the appropriate signaling cues are provided. Once cells in this quiescent state are activated by the requisite mitogens, it will usually take 15 to 20 h before the onset of S-phase. It is also important to remember that most cells have limited proliferative potential so that after growing and dividing for some time (perhaps 50-cell doubling would be a typical duration) they assume a nonproliferative state. Now cells will be destined to perform the specific function that their pattern of gene expression dictates. Such cells become terminally differentiated and are no longer capable of accessing the cell cycle. A minority of cells in multicellular organisms maintain a long-term undifferentiated status. These special cells, called *stem cells*, have a privileged status that allows them to evade differentiation and senescence.

2.3.1 Mitosis

Once a cell has performed DNA replication and has acquired the mass needed

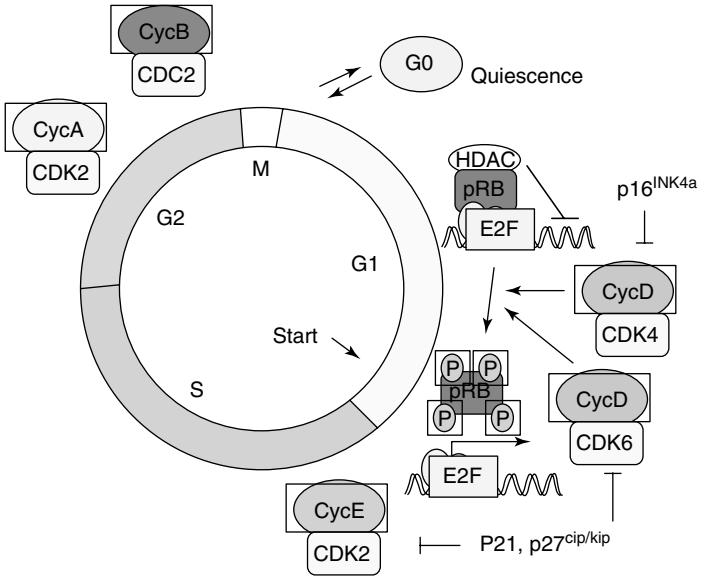

Fig. 2 The cell cycle. In proliferating mammalian cells, the cell cycle covers roughly 24 h. This growth cycle is depicted by the central ring, in which the amount of DNA in the cell is depicted (relative intensity of blue shading). The notable events of this cycle are the S-phase where DNA is replicated and the M-phase where chromosome segregation and daughter cell formation take place. These are separated by two gap phases – G1 and G2. Progression through the cell cycle is dictated by mitogenic signals from growth factors that interact with the cell cycle machinery, the critical components of which are shown here. Cyclin/CDK/C complexes drive the cycle. Kinase activities within the CDK proteins are responsible for regulating the downstream effects and the activity of the kinases is regulated by the cell cycle dependent expression of the cyclin proteins. The cell cycle machinery has many targets. For simplicity, the figure shows one major target, the cell cycle regulator Rb. Rb is phosphorylated by the cell cycle kinases and this activity releases Rb from complexes that suppress the transcription of critical proteins involved in proliferation, particularly DNA synthesis. Once Rb phosphorylation has activated this process, a cell is committed to pass through the cycle and on to mitosis. The activity of the cell cycle proteins is regulated by numerous other interactions such as those with the tumor suppressor proteins p21 and $p16^{INK4a}$. (See color plate p. xxix).

to generate two daughter cells, mitosis can begin. The onset of mitosis is driven by the cdc2/cyclinB complex. Major phosphorylation targets for this complex include histone H1 and lamin proteins. Modification of these proteins, together with numerous other modifications, drive chromosome condensation and disruption of the nuclear membrane. RNA synthesis is also switched off. Chromosome condensation begins late in G2; at this stage of the cell cycle, simple staining of DNA within the nuclei reveals the wormlike appearance of the condensing chromatin. The condensation process involves an axial retraction of the chromatin loops and

condensation along the chromosome axis. Chromosome condensation occurs during prophase and continues for about 30 min; as this process nears completion the nuclear membrane breaks down, marking the transition from interphase to mitosis. By late prophase, the chromosomes are fully condensed and are interacting with the mitotic microtubules. Microtubules function to adjust the position of the chromosomes until they are all aligned, at metaphase, across the center of the cell.

Chromosome condensation generates an elongated structure, which ensures that the kinetochores located within the centromeres of each chromosome are accessible to the microtubules that will eventually drag each daughter chromatid to the site where the two daughter nuclei will form. As the efficacy of this process is critical to the maintenance of genomic integrity, a mitotic checkpoint ensures that the chromatids are only able to separate once all kinetochores are attached via microtubules to the spindle. Prior to this point, a G2 checkpoint verifies that the replication process is complete. Once the kinetochores are fully engaged, the cohesin proteins that hold the sister chromatids together are released and the chromatids move from the metaphase plate toward the spindle poles; prior to this, topoisomerase II serves to resolve interlocked DNA loops that arise during replication. Microtubule and kinetochore-associated motor proteins, together with the dynamic properties of the microtubules themselves, provide the motive forces that reposition the daughter chromatids within the cell. The mitotic phase that involves migration of sister chromatids toward the spindle poles is called *anaphase* and this is followed by *telophase*, where chromosome decondensation begins. At this stage, the mitotic cell cycle machinery is destroyed and the new daughter cells form by cytokinesis.

2.3.2 Meiosis

In almost all cells, proliferation involves the duplication of a diploid chromosome set to form a tetraploid set, which is then separated, at mitosis, to form daughter cells that are once more diploid. Meiosis is a related process, which occurs in germ cells and serves to reduce the level of ploidy, so that on completing meiosis cells contain a single, haploid, chromosome set. Meiosis is a complex process, which not only reduces cell ploidy but also allows DNA exchange between homologous chromosomes to stimulate genetic diversity. Perhaps the easiest way to understand meiosis is to imagine the process as two consecutive mitotic events without an intervening S-phase. The cells that undertake meiosis are tetraploid. The first series of events – called *meiotic division one* – follow the same principle as mitosis but include a much longer prophase during which chromosome pairing and recombination take place; in human testes the duration of meiosis is roughly 25 days. The first meiotic prophase – during which time the nucleus remains intact – is traditionally divided into five sequential stages: leptotene, zygotene, pachytene, diplotene, and diakinesis. Homologous chromosome pairs synapse during zygotene and during pachytene, the resulting synaptonemal complex is thought to allow homologous recombination of the paired chromosomes to occur. The molecular details of this recombination process are poorly understood. The recombination complexes dissolve during diplotene to leave homologs that are attached at a small number of chiasma. The first meiotic division then proceeds through metaphase and anaphase and daughter nuclei are formed.

After a brief interphase, the second meiotic division follows according to the pattern described for a normal mitotic division. The overall process generates cells with a haploid DNA content and a small number of novel chromosomes that have arisen through recombination of chromosome homologues that were initially derived from the organisms' male and female predecessors.

3 Nuclear Structure

As the nuclear boundary might be assumed to define the nucleus itself a detailed understanding of the structure and function of the nuclear periphery is required to understand many features that define how nuclei work. In doing this, it is helpful to consider the nuclear periphery as being composed of three components:

1. The nuclear envelope is a double-membrane structure, with an outer membrane that is contiguous with the rough endoplasmic reticulum. Given this continuity, it is not surprising that areas of the outer nuclear membrane can be seen to be studded with ribosomes. The outer and inner lipid bilayers of the double envelope have common components but contain specific proteins that might be nuclear or cytoplasmic in location.
2. Over most of the nuclear surface, the two membranes of the nuclear envelope are separated by a fluid filled space that separates the membranes by about 50 nm. Over a small proportion of the nuclear surface, the inner and outer membranes are fused together. This fusion is seen to occur at structures called *nuclear pores*. These pores are the major routes of transit of any materials that must pass between the nucleus and the cytoplasm.
3. The nuclear face of the inner nuclear envelope is associated with a peripheral nuclear lamina. The lamina is composed of intermediate filaments of the lamin A/C and B proteins and is believed to play a role in the regulation of nuclear envelope structure and nuclear shape. Proteins that bind to the nuclear lamina also interact with chromatin so that through these adaptor proteins the lamina can also play a role in chromatin organization and the regulation of chromatin function.

3.1 Nuclear Pore Structure

A proliferating human cell has a few thousand pores and the number doubles in concert with doubling of chromatin during S-phase. Pores are disrupted during mitosis and the pore proteins are dispersed into about 12 pore subassemblies. Pores are rebuilt from these pore protein complexes during assembly of the new nuclear membrane at the end of mitosis.

In all eukaryotes, nuclear pores provide the gateway between the nucleus and cytoplasm. In mammalian cells, the pores are a megacomplex of about 150 MDa composed of roughly 50 different proteins (Table 3); the yeast pore has some 30 recognized pore proteins and it may be that some of the vertebrate proteins that have been classified as pore components are in fact transport factors. The general structure of a nuclear pore is shown in Fig. 3. The basic features of pore structure are:

1. The major structure of the core complexes is cylindrical with external

dimensions of 120 × 80 nm. This complex has a striking eightfold symmetry as well as providing the structure of the channel between the nucleus and cytoplasm, which serves to fuse the inner and outer nuclear membranes. The eight spokes of the channel are held together to form a major scaffold of the pore.

2. These spokes surround a central transporter complex that is ~60-nm high and 40 nm in diameter.
3. The cytoplasmic face of the pore complex has 8 cytoplasmic filaments that extend about 50 nm into the cytoplasm.
4. The nucleoplasmic face of the pore has 8 filaments of 100 to 150 nm that extend into the nucleus. In some situations, these appear to associate at their distal end to generate a basket-like structure at the nuclear face of the pore complex.

3.1.1 Pore Function

Nuclear pores are the gateways between the nuclear and cytoplasmic compartments. Small molecules are able to pass through the pores by simple diffusion. Studies on diffusion kinetics suggest that a cylindrical diffusion channel of ~9 nm exists between the pore spokes and the central transporter complex. Proteins or RNA–protein complexes that are ~50 kDa and smaller are able to pass through this diffusion channel, but larger complexes are not and must rely on active transport systems.

The components of the vertebrate pore complex and their probable location in the complex are shown in Table 3. During active transport, the critical steps involve the initial interaction of the nuclear transport complex – that is, the cargo – with the pore filaments that extend into either the nucleus or cytoplasm. The pore proteins are involved in active transport as described below.

3.2 The Nuclear Lamina

During the 1960s, it was recognized that nuclei from mammalian cells had a protein network between the nuclear envelope and peripheral chromatin. This network or lamina is composed of a branched network of polymerized lamin proteins.

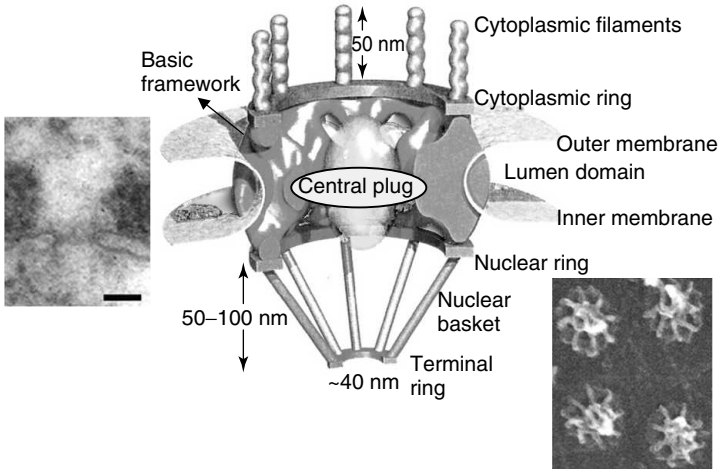

Fig. 3 The nuclear pore. The structure of the nuclear pore complex, shown here in cartoon form, was assimilated using a variety of electron microscopy (em) techniques. Details of the structure and the location of the constituent components are given in the text and in Table 3. The left inset (courtesy Francisco Iborra) shows a classical em thin section prepared in an epoxy resin, the bar is 100 nm. The nucleus occupies the upper half of the image. Note the densely stained heterochromatin lying against the nuclear membrane, the structure of the double membrane and the density of material at the pore. The right inset shows the inner nuclear face of an isolated nuclear membrane, visualized using a high-voltage scanning electron microscope. This shows the structure of the nuclear baskets and emphasizes the eightfold symmetry of the pore complex. The central image is reproduced from Izaurralde, E., Kann, M., Pante, N., Sodeik, B., Hohn, T. (1999) Viruses, microorganisms and scientists meet the nuclear pore, *EMBO J.* **18**, 289–296. With permission of Oxford University Press and the right inset is from Goldberg, M.W., Allen, T.D. (1992) High-resolution electron microscopy of the nuclear envelope – demonstration of a new, regular fibrous lattice attached to the baskets of the nucleoplasmic face of nuclear pores, *J. Cell Biol.* **119**, 1429–1440. With permission of Rockefeller University Press.

The lamins are classified as type V intermediate filaments (IFs), and like all intermediate filament proteins have a specific domain with an α-helical coiled-coil region flanked by nonhelical domains. The central coiled-coil domain is essential for assembly of the filaments. This process occurs initially through dimers and then through higher multimers, such that a mature IF of 10 nm in cross-section has ~32 monomers in its cross-section. During the assembly process, specific alignment of the IF protein monomers gives a repeat structure with ~23 nm periodicity. Major IF proteins in the cytoplasm of mammalian cells, such as vimentin, form very regular 10 nm (diameter) filaments that rarely branch. The nuclear lamins, in contrast, are highly branched and branches of smaller cross-section (i.e. suggesting filaments with fewer monomers in cross-section) are often seen. In addition to the peripheral nuclear lamina, nuclear lamin proteins

are also found within the nuclear interior. *In vivo* studies support the view that these, like the peripheral proteins, are assembled into structures that have rather slow rates of exchange. However, it is still unclear if this represents a lamin filament network that pervades the nucleus or local aggregates of lamin proteins that might serve a function that does not demand a contiguous ''nucleoskeleton.''

3.2.1 The Lamin Genes

The lamin proteins represent a small protein family that has increased in complexity during metazoan evolution. Simple eukaryotes, such as the yeast *S. cerevisiae,* do not have lamin proteins; perhaps the lamina evolved during the transition from a closed mitosis to open mitosis. The simple multicellular organism *Caenorhabditis elegans* has a single lamin gene, which is expressed in all somatic cells. Mammals have three lamin genes (*LMNA, LMNB1*, and *LMNB2*) that are processed to yield 7 isoforms. RNA processing – alternative splicing – of the *LMNA* primary transcript generates four A-type lamins – lamins A, AΔ10 (a splice variant without exon 10), C, and C2. Three B-type lamins, called *lamins B1–B3,* are encoded by the *LMNB1/2* genes. All vertebrate cells express at least one variant of the B-type lamin proteins. The A-type lamins, in contrast, are expressed primarily in differentiated cells so that patterns of lamins A, AΔ10 and C expression are developmentally regulated. Lamins C2 and B3 are found only in germ cells.

3.2.2 The Lamin Proteins and Filament Assembly

Like other members of the intermediate filament class of proteins, lamins have a central rod domain that consists mainly of heptad repeats. The coiled-coil structure that forms from these repeats drives the interaction of two monomers to form a coiled-coil dimer. This form is the basic building block for lamin filaments. Higher-order filaments form as a consequence of lateral interaction between the rod domains of the dimers. The rod domains are flanked by non-α-helical amino-terminal and carboxy-terminal domains. The latter contains a nuclear localization signal. Lamin proteins are also subjected to posttranslational modifications such as phosphorylation and most importantly are modified by isoprenylation, a modification that targets the lamin filaments to the nuclear envelope. This modification takes place on a special CaaX motif (not found in lamin C). Following cleavage after the cysteine residue the new terminal amino acid is modified by isoprenylation and methyl esterification.

3.2.3 Lamin Function

Various studies identify the structural features as a major role for the lamin proteins. It is notable, for example, that nuclei maintain their shape even after most of the nuclear contents have been removed. This and many other experiments suggest a role for the lamins in maintaining the mechanical stability of nuclei. The importance of maintaining a particular nuclear shape is not clear. Perhaps more important functionally is the possibility that the nuclear lamina can potentially define nuclear sites that have particular functional roles. Many proteins are known that act as adaptors that link the lamina to the nuclear envelope and components within chromatin to the lamina. Heterochromatin – which is transcriptionally inert – is commonly associated with the nuclear periphery and this

location might have important implications for the regulation of gene expression. A-type lamins bind the retinoblastoma protein and other transcriptional repressors and may play important roles in regulating gene expression through spatial organization.

Other experiments support the fascinating possibility that nuclear lamins might be involved in the processes of DNA and RNA synthesis. The experimental evidence involves the introduction into cells – by microinjection – of bacterially expressed lamin proteins that have amino-terminal deletions. The microinjected proteins are engineered so that they interact with the endogenous proteins to disrupt stable filament formation. It has been reported that when the lamin filaments are disrupted in this way, DNA synthesis and RNA polymerase II-dependent RNA synthesis are also disrupted. One explanation for this is that lamin filaments or perhaps smaller local aggregates of the lamin proteins play some structural role within the active centers of DNA and RNA synthesis.

3.2.4 Lamin-associated Proteins

Many proteins are known to interact with the lamins to influence lamin function. These might be classified into two broad groups. Integral proteins of the inner nuclear membrane are the first group and include various isoforms of lamin-associated protein 2 (LAP2), LAP1, lamin B receptor (LBR), emerin, otefin, MAN1, Nurim, nesprin, RING finger-binding protein, A-kinase anchoring protein 149, and p19 (an isoquinoline-binding protein that is also found in the endoplasmic reticulum). The second group contains proteins that associate with the lamins but are not membrane components. This group includes germ cell-less (GCL), young arrest (YA), PP1 phosphatase and the transcription factor Oct1.

The nuclear lamina is known to play a role in chromatin organization and the lamins can be shown to bind DNA elements called *nuclear matrix* and scaffold attachment regions (S/MARs) *in vitro*. The LAP2 isoforms LAP2α and LAP2β bind to chromatin. Chromatin binding involves two motifs on the LAP proteins, a chromatin binding domain and a LEM domain. The LEM domain is a region of about 40 amino acids that is also found in emerin, otefin and MAN1. The LEM domain interacts with other chromatin-associated proteins such as BAF – and might then influence chromatin architecture and function.

3.2.5 Lamin Mutants

Knockout mice for the lamin A/C gene has been developed to study lamin function. Null mice appear normal at birth, but soon after develop severe growth defects. At about one month after birth the null mice display reduced mobility and a stiff walking posture. No mice survive beyond two months. From histological examination, it is clear that the affected mice have skeletal and cardiac muscle wasting and reduced white fat. Fibroblasts from the lamin-A knockout mice show abnormal nuclear blebs, which appear to result from a dramatically reduced amount of lamin proteins. The lamin-associated proteins LAP2 and NUP153 (a nuclear pore complex protein) are also significantly reduced. An abnormal distribution of emerin is also seen, together with some uncharacteristic features of heterochromatin organization. These features of knockout mice are reminiscent of symptoms seen in human patients with Emery Dreifus muscular dystrophy (EDMD). Indeed, mutations in *LMNA* have recently

been show to be causative for the autosomal dominant form of this disease. About 50 mutations within *LMNA* have been described that lead to disease states such as EDMD and closely related disorders. Interestingly, lamin mutations seem not to affect all cell types, and while knockout mice die soon after birth, it is notable that individuals with lamin mutations live into adulthood. This may not be surprising as natural selection allows the accumulation of mutations that are not lethal. It is interesting to speculate that mutant lamins weaken the structure of the lamina to yield fragile nuclei. These might be especially susceptible to damage in cells such as muscle and tendon that are put under significant stress during muscle contraction.

3.3 Biogenesis of the Nuclear Envelope During Cell Proliferation

The process of cell division inevitably demands that a series of profound structural changes will be required to generate two genetically identical daughter cells during mitosis. Prior to mitosis, chromosomes are dispersed throughout the nuclear interior. Before the new daughter cells can form, the chromosomes must condense so one of each of the daughter chromatids (i.e. the two equivalent products of DNA replication for each chromosome) can pass to the daughter cells. The cell cycle proteins, and critically at this part of the cell cycle cdc2 and cyclinB, predominantly through changes in phosphorylation, drive changes in chromatin structure that lead to chromosome condensation. Other changes lead to a concomitant dissolution of the nuclear periphery. The critical events needed to achieve this involve changes in the structure of the nuclear lamina. Changes in phosphorylation of the lamin proteins cause disruption of the lamin filament network. Loss of the chromatin stabilizing properties of the lamin-chromatin interactions allows an increase in chromatin mobility so that chromosome condensation is not impeded. Moreover, as the lamina disrupts, stabilizing contacts between the lamina and nuclear envelope are lost. The new dynamic capabilities of the nuclear envelope then allow the membrane to merge with the envelope networks of the endoplasmic reticulum. During this process the nuclear pores are disrupted into a small number of discrete pore subassemblies. This dissolution of the nuclear membrane and the concomitant condensation of chromosomes marks the early stages of mitosis. While this is by far the most common course of events during a eukaryotic mitosis it should be noted that some simple model eukaryotes – such as the yeast *S. cerevisiae* – have a closed mitosis where the nuclear membrane remains ostensibly intact during chromosome separation.

During mitosis, once the chromosomes have migrated to the poles of the cell, a central constriction in the cell membrane leads to the formation of the two new daughter cells. The cell cycle machinery now drives nuclear reconstruction. In essence, the new nuclei form through a program that is the reverse of the events that preceded the onset of mitosis. As the chromosomes begin to expand, patches on new nuclear lamina are thought to become associated with the chromatin and these then engage the endoplasmic reticulum, which is extruded to surround the chromosomes, eventually to form the new nuclear envelopes. Lamin B appears to associate with chromatin early during the assembly process while lamin A seems to remain in the cytoplasm until nuclear membrane assembly is complete – when

it is imported through the nuclear pores. Assembly and maturation of the lamina continues for an hour or two into the G1 phase. The fluid properties of the nuclear membrane eventually lead to formation of a complete double envelope. While this process is ongoing, nuclear pores are assembled into the envelope. Soon after cell division, a fully operative nuclear envelope is formed.

3.4 Nuclear Transport and Karyopherins

The fact that eukaryotes have evolved to confine the genetic material within a specialized organelle – the nucleus – demands that mechanisms must exist to regulate the passage of information between the nucleus and cytoplasm. This is self-evident as the products of gene transcription must pass to the cytoplasm for translation and all the proteins that control and direct gene function must pass in the opposite direction, moving into the nucleus from the cytoplasm where they are synthesized.

This nuclear-cytoplasmic traffic takes place through the nuclear pores. The detailed structure of these pores has been elucidated and, as we saw earlier, provides a structural framework that can be used to elaborate the mechanisms of nuclear pore-mediated transport. The basic principles of transport are well known, though some details remain to be confirmed. The first point to emphasize is that nuclear pores do not provide an absolute barrier between the nucleus and cytoplasm. In fact, small molecules and proteins that have a size below ~50 kDa are able to diffuse through the pores. Any proteins that are larger than this, and protein nucleic acid complexes undergo either nuclear import or export using specific transport mechanisms. This active process involves nuclear localization and export signals that are recognized by the import/export machinery. The nuclear localization sequence of the SV40 virus large T antigen was the first to be analyzed in detail. In this protein, the amino acid sequence: Pro-Pro-Lys-Lys-Lys-Arg-Lys-Val directs nuclear accumulation of the protein. In other proteins, it is not uncommon to find bipartite localization signals where two short lysine and arginine-rich regions are separated by ~10 intervening amino acids.

The molecular details of the protein transport process are by far the best understood. The key components in this process are the karyopherin proteins that operate as shuttling transport receptors. The simple eukaryotes *S. cerevisiae* is known to have 14 karyopherin proteins and at least 20 have been described in human cells. Karyopherins can be further subdivided into importins and exportins. As the names imply, these are largely dedicated to either the nuclear import or export pathways; though examples are known that can transport different cargoes across the nuclear pores in both directions.

3.4.1 The RanGTP/GDP Cycle

Movement of a molecule across the nuclear pore will generally take place against a concentration gradient and involves ATP hydrolysis. The basis of this process relies on the way in which the karyopherin–cargo complexes interact with the pore proteins and subsequently pass through the pore to be released on the other side. The behavior of importins and exportins during this process is regulated by the small GTPase Ran. More specifically, substrate binding and release by the karyopherins is regulated by the asymmetrical distribution of the GTP- and GDP-bound states of Ran.

These states establish a RanGTP gradient across the nuclear pore, in which Ran inside the nucleus is predominantly GTP-bound, while the one outside is mostly in the GDP-bound state. This gradient is manipulated by a variety of accessory factors that together regulate transport. The most important feature of the RanGTP/GDP cycle is that GTP loading occurs in the nucleus while hydrolysis occurs in the cytoplasm. The Ran guanine nucleotide exchange factor (RanGEF) called RCC1 catalyzes GTP loading, while RanGTP hydrolysis is performed by the RanGTPase activating protein RanGAP together with accessory proteins RanBP1 and RanBP2. RanGAP and RanBP1/2 are restricted to the cytoplasm. This asymmetrical distribution of the Ran regulators establishes a RanGTP gradient such that each molecule of Ran that enters the nucleus will be rapidly converted to the GTP-bound state, while RanGTP moving out of the nucleus will be converted to RanGDP on entering the cytoplasm. The magnitude of this gradient can be estimated using Ran biosensors that use fluorescence resonance energy transfer (FRET) to probe structural changes during transport. This approach suggests that the concentration of free RanGTP in the nucleus is at least 200-fold greater than that in the cytoplasm.

The RanGTP gradient provides the position information that drives nuclear transport. During import, the importins will bind to their substrates in the absence of Ran and after translocation release the substrate on binding RanGTP in the nucleus. Here, the RanGTP operates as a kind of exchange factor and the importin–RanGTP complex that forms is recycled back to the cytoplasm. During export, the exportins only bind to their cargoes in the presence of RanGTP. The RanGTP gradient ensures that this occurs almost exclusively in the nucleus. On the cytoplasmic side of the pore complex, the exportin/RanGTP/cargo complex decays following RanGTP hydrolysis that is driven by RanGAP and RanBP1/2. RanGDP returns to the nucleus in a complex with a Ran importer protein called NTF2. Once inside the nucleus, RanGDP is once again converted to the GTP-bound form, to release NTF2 so that a new cycle of transport can begin.

3.4.2 RNA Export Pathways

In contrast to the well-characterized mechanisms used to regulate protein transport through nuclear pores, many details of the mechanisms for RNA transport remain sketchy. The importance of this should not be underestimated as it clearly represents a critical point of regulation in the control of gene expression. In addition, it is well known that many independent pathways regulate the transport of different classes of RNA–protein complexes – this could be potentially very complex allowing the differential regulation of specific classes of RNA transcript in response to a variety of developmental and growth regulatory cues.

Basic details of the primary mechanisms that control mRNP export have been elucidated. The molecular interactions that underlie this process are dependent on events that take place at the site of mRNA synthesis. The critical components are small proteins that are part of a much larger complex that is deposited on the mRNA during splicing. The complex called the – 20/24 complex because of its location at about 20 nucleotides upstream of the exon–intron junction contains a number of proteins, but includes the protein Aly. Aly interacts specifically with TAP/mex67, which serves as a major export complex for mRNAs. It is important to recognize that

mRNA export is coupled to many of the proceeding steps of gene expression. In broad terms, the pathway that delivers mature mRNAs to the cytoplasm is influenced by promoter strength, the RNA polymerase complex that performs synthesis, transcriptional elongation, as well as down stream processing events such as RNA splicing and polyadenylation. A significant aspect of this pathway reflects the fact that mRNAs are retained at the transcription site until the required processing events have been performed. This is likely to be part of the ''quality control'' process, which ensures that only authentic mature mRNAs are exported to the cytoplasm.

Apart from the general export factors, many proteins have been described that interact with different classes of RNA to regulate RNA export. Certain factors regulate the export of different classes of mRNA and others are essential for the export of ribosomes and RNA–protein complexes that contain RNAs transcribed by RNA pol III.

3.4.3 Nuclear Transport – Facilitated Diffusion

We have looked in some detail at the molecules involved in nuclear transport without concern for the mechanisms that drive the transport process itself. It was noted above that the nuclear pore is essentially ''open'' to small molecules. Transport that is mediated by karyopherins is perceived as being a form of directed diffusion – or facilitated translocation. The critical question to address here is how do pores exert a high degree of selectivity on the nuclear transport receptors while excluding proteins that do not contain the appropriate receptor signals. A critical first step requires an association – binding – of the transport receptor to target molecules within the pore complex. These interactions have been characterized in detail. What is not clear, however, is why this primary interaction would inevitably lead to the cargo being directed through the pore. Models of facilitated translocation suppose that selectivity – gating – is achieved through interactions between the transport complex and particular protein motifs in the pore proteins – called *FG-repeats*. The FG-repeats are proposed to provide a sort of hydrophobic plug that severely reduces the efficiency with which molecules that are not destined for transport are able to pass through nuclear pores. The receptor/cargo complex, in contrast, by virtue of its structure and interaction with other pore components is able to diffuse through this region of the pore. Though the details by which selectivity is achieved remain to be refined, changes in pore permeability following treatment with organic solvents are consistent with a role for a hydrophobic meshwork (provided by the FG-repeats) inside the pore channel.

3.5 Nuclear Architecture and Nuclear Compartments

3.5.1 Nuclear Compartments

In mammalian cells, the nuclear membrane defines two major cell compartments – the nucleus and cytoplasm – that have quite distinct structural characteristics (Fig. 4). The cytoplasm gives an impression of being highly structured with many discrete organelles such as mitochondria and lysosomes and has other regions that contain dense clusters of ribosomes (each ribosome is 25 nm in diameter) performing protein synthesis. The nucleus is also structured, but the basic principles that define nuclear structure

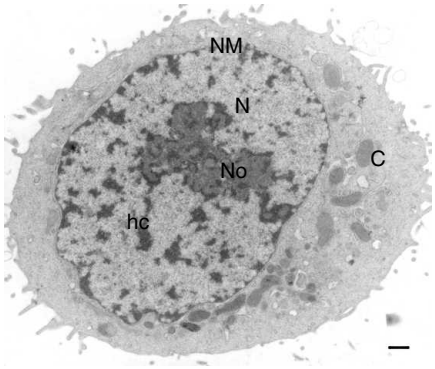

Fig. 4 The mammalian cell. Proliferating HeLa cells (this is a transformed human cell line) were fixed, stained, and processed using standard electron microscopy techniques. Thin sections were then prepared and inspected. This typical cell section shows a central nucleus (N) – typically of about 10 µm diameter in an equatorial section – which is separated from the cytoplasm (C) by a double nuclear membrane (NM). The nuclear membrane is studded with a few thousand nuclear pores that allow molecules to pass between the two major cell compartments. Note that the cytoplasm contains a large number of membrane-bound organelles – the most conspicuous of these, the mitochondria, are dark staining and typically about 1 µm in diameter in this example. The nucleus does not contain any membrane-bound subcompartments. Even so it is highly organized. In this type of image, the most obvious substructure is the nucleolus (No). In this example, a single large nucleolus occupies the center of the nucleus. The nucleolus is densely staining and has three distinct subcompartments: the most densely staining regions are called the *dense fibrillar component*; these structures are generally crescent shaped and a few hundred nm in size. The dense fibrillar components represent the nascent transcripts that surround the much paler fibrillar centers. The processed ribosomal RNAs are assembled into ribosomal subunits in the granular component, which comprises the bulk of the nucleolus. Dark staining clumps of material that lie against the surface of the nucleolus, the nuclear face of the membrane and are scattered throughout the center of the nucleus are dense heterochromatin (hc). The remainder of the nucleus has an amorphous appearance and little obvious structure. This nucleoplasmic region contains the transcribed genes in euchromatin and is composed of a mixture of this open chromatin and the interchromatin material, which is predominantly RNA and protein. The bar is 1 µm.

are quite different. The nucleus does not contain subnuclear organelles – by definition, organelles are enclosed by a membrane. Instead, the nucleus has numerous discrete zones or compartments where particular functions are performed. The nucleolus provides an excellent example of this organizational theme. Indeed, it is not unusual for the nucleoli to be the most conspicuous interphase structure in a mammalian cell.

3.5.2 **The Nucleolus**

Nucleoli are sites of ribosomal RNA synthesis and processing and also centers of biogenesis for the ribosomal subunits. Clearly defined subcompartments within nucleoli reflect the centers where these different activities are performed. Mammalian cells generally contain 1 to 5 nucleoli; the number will usually reflect the proliferative status of a cell and might be used by histologists as an indicator

of proliferation in cancer diagnosis. Nucleoli range in size from 0.5 to 5.0 μm and are assembled around the active ribosomal RNA genes. Each diploid human cell has about 300 copies of the ribosomal RNA locus. Each locus contains a single transcription unit of 13.3 kb, which is processed posttranscriptionally to generate 3 RNA molecules – the 28S, 18S and 5.8S (in vertebrates) rRNAs – which, together with 5S RNA are the structural RNAs that dictate ribosome assembly and function. The genes are located on 5 human chromosomes at the subtelomeric regions of c13, 14, 15, 21, and 22, where they are found in short tandem arrays – typically as clusters of 3 to 5 rDNA repeats. In most proliferating human cells, only about one-third of the total cell complement of ribosomal genes is active at any time. In proliferating cells, nucleoli form as ribosomal RNA synthesis is reestablished, soon after cell division is complete. Ribosomal RNA genes retain associated transcription factors throughout mitosis and these provide efficient targets for the assembly of transcription complexes at the onset of interphase. As transcription recovers, the components involved are believed to interact to form the characteristic nucleolar morphology. Each active center is defined by a fibrillar center (FC) that has a distinct fibrogranular appearance and is rich in the machinery that is required to generate rRNA. The surface of each FC is coated with a much denser dense fibrillar component (DFC) that contains the nascent transcripts and their associated proteins. The transcribed rRNA genes lie along the interface of the FC and DFC and a single FC will typically have 3 to 5 associated active genes.

Ribosomal RNA genes are the most active transcription units in mammalian cells. It takes about 3 min to complete synthesis of the primary transcript, and polymerases are engaged onto the promoter with such efficiency that each active gene has 100 to 120 engaged RNA polymerase I complexes. In order to achieve this level of synthesis, new initiation events must occur at roughly 1.5-s intervals; the residence time of the major transcription factors in the FC is ~5 s and the residence time for RNA polymerase I on the promoter is roughly 1 s. The primary transcripts are processed to generate mature ribosomal RNAs. This is an extremely complex process that involves a number of specific cleavage events and RNA modifications, typically methylation. These posttranscriptional events are directed by at least 100 special small nucleolar RNA–protein complexes (snoRNPs). The mature rRNAs then associate with the requisite ribosomal proteins and begin their passage from the synthetic center to the cytoplasm. For the early stages – about 1 h – of this migration they remain nuclear and occupy the nucleolar granular component (GC), a morphologically punctate or granular zone that surrounds the active rRNA transcription centers. Eventually, the mature 40 and 60S ribosomal particles pass from the nucleolus and through the nucleoplasm to the nuclear periphery from where they exit the nucleus through nuclear pores.

3.5.3 Nuclear Bodies and Domains

Other nuclear structures have been described as nuclear bodies and domains. Many cell types have a small number (typically 1–5) of coiled or Cajal bodies, which are generally spherical, measure 0.3 to 1 μm across and in cross-section, appear as a network of coiled fibers. Coiled bodies are found in both animals and plants and contain many different proteins, including p80 coilin (the diagnostic

marker), various transcription factors, as well as small ribonucleoproteins. These bodies are not transcriptionally active, and are thought to play a role in the biogenesis of small nuclear RNA–protein complexes (snRNPs) and in the nuclear trafficking of snRNPs and snoRNPs. RNP complexes that are essential for mRNA splicing (U1, U2, U4/U6, and U5 snRNPs), rRNA processing (U3 and U8 snoRNPs) and histone mRNA end formation (U7 snRNPs), all localize to the Cajal bodies. Possible roles for these structures are suggested by the fact that they are often seen to associate with specific internuclear sites, such as the histone loci and U1/U2/U3 gene cluster.

PML bodies are defined by their content of promyelocytic leukemia (PML) protein. They are similar in size to coiled bodies but are usually more abundant – mammalian cells commonly have 10 to 20 PML bodies. PML bodies have also been referred to as the ND10 compartment, PODs (PML oncogenic domains) and Kr bodies. In addition to the PML protein, these structures also contain proteins such as: Sp100; SUMO1; HAUSP; and CBP. Though the precise role of PML bodies is unclear, it has been suggested that they will play some role in transcriptional regulation. Interestingly, these domains are common targets of viral genomes during the early infectious stages in mammalian cells.

Pc-G bodies that contain polycomb group proteins such as RING1, BMI1, and hPc2 have been observed to associate with pericentromeric heterchromatin. Gems (gemini of Cajal bodies) generally lie adjacent to the Cajal bodies and are characterized by the presence of the survival of motor neurons gene product (SMN) and an associated factor Gemin2. Other sites have been described that might be classified as transcription superfactories. The OPT (Oct1/PTF/transcription) domain provides a good example. Immunofluorescence shows that in HeLa cells, the transcription factors Oct1 and PTF are found in 1 to 3 large domains (diameter $\sim$1.5 μm) that appear during G1 phase and disappear in S-phase. Each OPT domain typically contains 2 to 3 transcription sites where BrUTP is incorporated into nascent transcripts, as well as RNA polymerase II, TBP, and Sp1. Some chromosomes, notably chromosome 6, are found to be closely associated with the OPT domains. But while nuclear bodies have raised much interest, the extent to which they define essential functional compartments remains a matter of debate. The Cajal bodies exemplify this, as these structures can be disrupted in living cells or transgenic animals without obvious detriment to the hosts. Hence, the bodies, as structures, might not be absolutely crucial to the functions that are performed by components that are normally found within them.

3.5.4 Nuclear Speckles

Nuclear compartments such as nuclear bodies are not membrane-bound. Instead, they appear to persist because of the "self-assembly" characteristics of their components and architectural constraints imposed by nuclear and chromosome structure (see below). Nuclear speckles/interchromatin granule clusters (IGCs) provide an excellent example of this architectural theme. (Speckles were defined using light microscopy and immunofluorescence and were later found to be equivalent to the IGC that had been visualized using electron microscopy.) This compartment is especially rich in proteins required for RNA splicing – such

as the SR protein, family, which is defined by a specific serine and arginine rich motif – and occupies the interchromatin spaces where the proteins may accumulate to form large, clustered aggregates. Once formed, these aggregates – the speckles or IGCs – are stable in that they occupy a particular area of nuclear space over many hours. This spatial stability is seen even though the components within each site are in a continual state of flux. However, the IGCs are also plastic and can change dramatically under conditions in which RNA synthesis is inhibited and the need for splicing is lost; if cells are treated with the transcriptional inhibitor α-amanitin, the speckles lose their complex surface texture and collapse locally to form more dense spherical aggregates. This and the fact that highly active genes are commonly found at the periphery of speckles imply some functional link. Interestingly, cells that overexpress the serine-arginine (SR) protein kinase cdc2-like kinase (Clk)/STY exhibit disrupted speckles. This kinase hyper-phosphorylates a major IGC component, the nuclear SR proteins, which, as a result move out of the IGCs to diffuse throughout the nucleus. Cells without IGCs show no obvious defects in short-term RNA synthesis. However, under the same conditions RNA FISH to a specific transcript shows that splicing, assessed using a probe to an exon–exon junction, is severely impaired. This implies that splicing factors originating from a diffuse nucleoplasmic pool are not competent to perform splicing in vivo and that the organization of the IGC compartment is critical to this process.

3.5.5 Active Sites – Synthetic Factories

Transcription factories It is generally accepted that mammalian nuclei are highly compartmentalized and that the structure of different nuclear domains is implicit to their function. As we have seen, nucleoli provide the outstanding example of a nuclear compartment that serves a specific function. Nucleoli are dedicated to the efficient synthesis of a single primary RNA transcript and the products generated from this transcript by RNA processing are fundamental to ribosome assembly and function. Within nucleoli, morphologically distinct compartments define the active centers, where, as many as 500 engaged polymerase complexes are found within a typical FC/DFC complex. In terms of structure, the nucleolus represents a nuclear compartment that is dedicated to the synthesis and processing of a specific product.

This might lead us to ask if the same principle applies to transcripts that are synthesized and processed throughout the nucleus. Given the relative sizes and complexity of the corresponding sites, it is not surprising that the architecture of the nucleoplasmic transcription centers is less clearly defined. Classical electron microscopy techniques have shown that gene expression generally occurs at the borders of condensed chromatin in association with perichromatin fibrils. The ability to label the nascent RNA (Fig. 5) using BrUTP *in vitro* or BrU *in vivo* has shown that a proliferative mammalian cell has some 500 to 1000 active sites of RNA polymerase II activity for each haploid chromosome set. As cells have roughly 10 times the number of active RNA polymerase II holoenzyme complexes, each active center must represent a nuclear compartment in which the transcripts from groups of genes are generated and processed together. This spatial coordination of the different steps required to produce mature mRNAs at specific nuclear sites forms the basis of the concept of transcription ''factories'' where transcripts

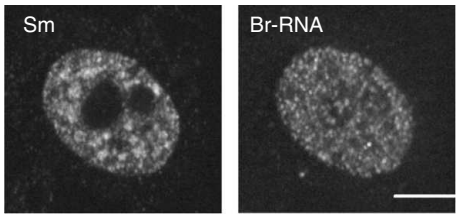

Fig. 5 Nuclear compartments and transcription. HeLa cells growing on glass were permeabilized in an isotonic buffer and transcription performed for 15 min in the presence of BrUTP. Samples were fixed and immuno-labeled for Br-RNA containing sites (right) using a red fluorescence dye and sites containing the auto-immune antigen Sm (left) using a green fluorescent dye. The two colors were recorded in a single 700 nm section of the nucleus using a laser scanning confocal microscope-gray-scale images of the two channels are shown. Note the classical ''speckled'' distribution of the Sm protein and the complexity of the transcription sites; the two areas that do not stain with Sm are nucleoli. The bar is 5 µm. See Pombo, A., Cook, P.R. (1996) The localization of sites containing nascent RNA and splicing factors, *Exp. Cell Res.* **229**, 201–203 for details. Published with permission of Academic Press.

are polymerized, processed and assembled into the required mRNA–protein complex before being released for export to the cytoplasm. For a typical transcript, events occurring at the transcription site take roughly 15 min to complete.

A likely corollary of this arrangement is that the transcription centers form a functional nuclear compartment that is spatially structured by an association with a component of the interchromatin compartments – perhaps a nucleoskeleton. Hence, during transcription the chromatin loops must be locally dynamic as RNA synthesis forces the gene to progressively associate (i.e. from promoter to 3′ end) with the synthetic center. The idea that genes might be associated with the active center during synthesis and displaced from it thereafter defines a type of spatially determined ''transcription cycle'' within which the interplay between chromatin dynamics and promoter bound factors will dictate levels of gene expression. The dynamic behavior of transcription factors will also be central to this control. Interestingly, some classes of transcription factor can be shown to associate with chromatin only transiently, whereas others are more stable, and might even remain bound to chromatin throughout mitosis. Factors such as TBP (TATA binding protein), which fall in the second category, are ideal candidates to mark active genes and regulate the association of these genes with transcription sites.

Replication factories DNA replication provides an interesting insight into how nuclear structure and function can be linked. We will see that DNA foci provide the best candidates for any structural units of chromosome structure (below). However, it is also important to recognize that the organization of these structures might be central to both the replication process and how the replication program proceeds. DNA foci contain small groups of replicons, which operate as spatially stable replicon clusters and provide targets for the assembly of replication factories. Like transcription factories, these arise through DNA–protein and protein–protein interactions that generate nuclear sites in which DNA synthesis can be performed with

optimal efficiency. These active centers are also spatially structured through their association with the nucleoskeleton. The modular structure of replicon clusters also provides a mechanism for replication to spread in a predetermined way from one bank of replicons to the next until the S-phase is complete.

Aspects of crosstalk between nuclear structure and function are of particular interest when considering how the S-phase program might be established. The importance of nuclear space in setting up the S-phase program is most evident in *S. cerevisiae*, in which the subnuclear position of replication origins in early G1 phase of the cell cycle determines whether origins are used either early or late in S-phase. In mammalian cells, the early replicons are selected during the first one-third of G1 phase of the cell cycle, prior to the commitment to engage the cell cycle. Two critical events appear to define the replication program and these are believed to depend on the complex interplay of chromosome structure, chromatin organization, and perhaps even global nuclear architecture. Replicons that are activated at the onset of the S-phase and most probably the downstream replication program are established during the first 2 h of G1 phase of the cell cycle. This ''temporal decision point'' coincides with the period when chromosomal territories reestablish their interphase structure and transcriptional potential. The process of defining an S-phase program is distinct from the process that establishes active origins of DNA replication. This second process also occurs in early G1 phase in mammalian cells and is thought to involve the binding of the origin recognition complex (ORC) to particular chromosomal sites.

In human cells, the assembly of replication factories begins late in the G1 phase of the cell cycle and appears to take about 15 min. The cell cycle machinery is responsible for the cues that initiate both the assembly process and initiation of DNA synthesis. The replication machinery is recruited to appropriate DNA foci – in mammalian cells only about 10% of possible origins are activated at the onset of the S-phase – through an association with ORCs on the DNA. All of the components needed for synthesis are recruited to the factories as a consequence of protein–protein interaction. For many of the replication components, factory-targeting sequences have been defined. As many replicons are replicated in each factory (early S-phase DNA foci contain ~5 replicons and later ones many more) the structure of the complex dictates that chromatin must move into the active center, which itself is static. This view can be confirmed using GFP-PCNA to analyze the spatial dynamics of replication sites in living cells. This demonstrates that the foci, once assembled, tend to be spatially stable, with the PCNA (Fig. 1) molecules that are assembled into the synthetic complex during initiation remaining at the active site until synthesis is complete. Once replication at a site is complete, the active center will disassemble. Often a new active center is then seen to assemble *de novo*, at an adjacent site. This principle underlies a proposed domino effect for a replication program, in which local changes in chromatin architecture dictate how replication proceeds until the S-phase is complete. In mammalian cells, S-phase lasts for about 10 h, while DNA synthesis from a typical origin will continue for about 1 h. As S-phase proceeds, the genome is reproduced in a predictable order so that defined chromosomal regions are duplicated at particular times during early, mid- or late S-phase (Fig. 6).

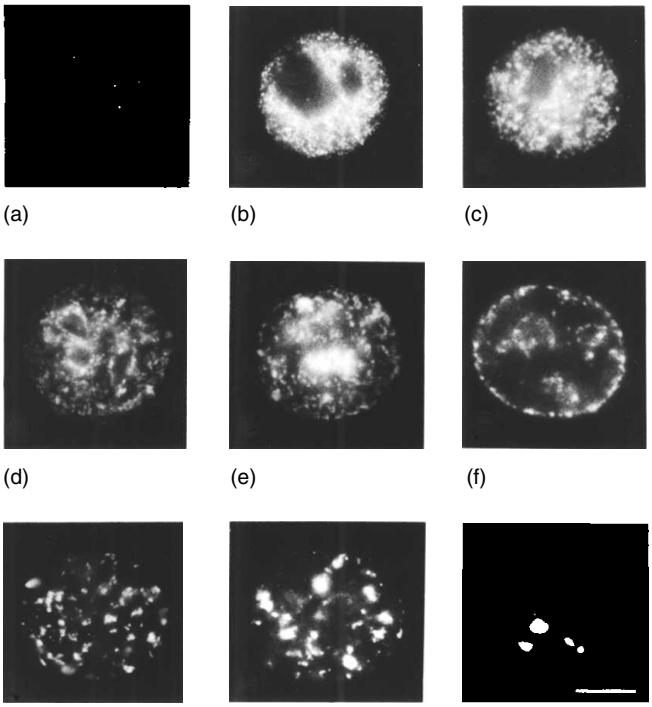

Fig. 6 The S-phase program. During S-phase, different classes of DNA elements are replicated at specific times. Chromatin with the majority of transcribed genes is replicated over the first ~4 h of the S-phase. During this period active sites of DNA synthesis are in discrete foci dispersed throughout the nuclear interior (a–c). These are designated early or type 1 replication patterns. During mid S-phase (d–f), replication switches to peripheral inactive chromatin. These mid S-phase patterns are also referred to as type 2 (d–e) and type 3 (f) patterns. During late S-phase (g–i) the replication of extended blocks of constitutive heterochromatin occurs throughout the nuclear interior. These late S-phase patterns are also referred to as type 4 (g–h) and type 5 (i) patterns. Encapsulated HeLa cells were synchronized at the onset of S-phase and replication sites labeled at 1 h intervals for 10 h. Images shown are replication sites labeled in permeabilized cells – using biotin-dUTP. (Reproduced from Hozak, P., Jackson, D.A., Cook, P.R. (1994) Replication factories and nuclear bodies: the ultrastructural characterization of replication sites during the cell cycle, *J. Cell Sci.* **107**, 2191–2202. With permission of the Company of Biologists. The bar is 5 μm.)

3.6 Chromosome Territories

It has been known for many years that chromosomes occupy discrete regions within interphase nuclei. Over the past 20 years, the idea that interphase chromosomes occupy discrete nuclear ''territories'' has been confirmed using a number of techniques. A major advance in the analysis in nuclear architecture came from the development of fluorescence in situ hybridization (FISH) techniques for ''chromosome painting.'' This process uses the unique sequences from purified chromosomes as probes to identify the location of particular chromosomes in fixed nuclei. The probe DNA is tagged with a modified DNA precursor analog – such as biotin-dUTP – prior to hybridizing to the fixed cell (with denatured target DNA) and is subsequently visualized using antibodies to biotin and secondary antibodies coupled to a fluorochrome that can be visualized by light microscopy. This technique confirmed that chromosome territories from mammalian cells appear to have distinct borders with little mixing of chromatin from adjacent territories. The territories themselves appear to be subcompartmentalized so that the space occupied by individual chromosome arms and even R and G bands within these arms might be defined within individual territories. The general principle of chromosome territory organization can be confirmed using a variety of DNA labeling techniques, using precursors that can be visualized in both fixed and living cells (Fig. 7).

The existence of chromosome territories begs the question: do interphase chromosomes occupy specific nuclear locations that could influence chromatin function? The answer to this appears to be partly yes and partly no. Territories do not generally occupy specific positions. However, gene activity does appear to influence chromosome location, such that chromosomes with a high density of active genes tend to be located toward the nuclear center, whereas those with a low density tend to lie closer to the nuclear periphery. The smaller chromosomes also show a tendency to occupy the nuclear center; note that for those chromosomes with ribosomal RNA gene clusters, location is determined by their association with nucleoli, which generally tend to be situated centrally in mammalian nuclei. Studies on cell populations show that individual chromosomes do not assume precise locations. However, when an individual mitotic event is followed, the arrangement of chromosomes in the two daughter cells is very similar to that of the mother nucleus immediately prior to mitosis. This implies that the mechanics of mitosis incorporate a mechanism for maintaining chromosome position.

So interphase chromosomes occupy discrete territories with preferred locations that can be maintained during cell division. However, this should not be taken to confirm that chromosomes are static structures. In fact, this is far from the truth; locally, the chromatin within each chromosome territory can be very dynamic. Moreover, while the vast majority of DNA from an individual territory remains within the defined zone, there are instances where chromatin escapes from its territory to form loops that might spread 1 to 2 μm into the surrounding nucleoplasm. These loops will generally contain a Mbp or more of DNA and commonly have an extruded or elongated appearance suggesting that they might occupy the interchromatin space that lies between adjacent territories. Chromatin loops of this sort are

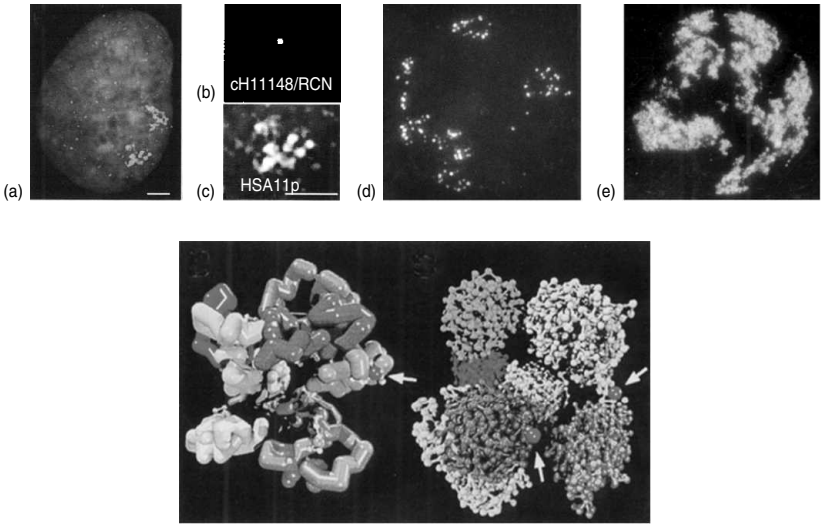

Fig. 7 The structure of chromosome territories. (a–c) show a high-resolution FISH analysis to demonstrate the organization of chromosome territories. In this example (a), the chromosome painting probe was generated from the short arm only of chromosome 11 (HSA11p) and indirectly labeled using a green fluorescent dye. Hybridization was also performed using a much shorter cosmid probe, to the ubiquitously expressed *RCN* gene from the WAGR locus of human chromosome 11, labeled with a red fluorescent dye. The relative positions of the red and green fluorescence are shown in the grayscale images in (b) and (c). Note that the expressed region is located close to the center of the chromosome territory and is separate from the dense chromatin regions, in this primary human fibroblast. The bars are 2.5 μm. From Mahy, N.L., Perry, P.E., Gilchrist, S., Baldock, R.A., Bickmore, W.A. (2002) Spatial organization of active and inactive genes and noncoding DNA within chromosome territories, *J. Cell Biol.* **157**, 579–589, with permission of Rockefeller University Press. (d–e) show the DNA foci that were labeled in HeLa cells at the onset of S-phase for 20 min or 10 h using Bromo-deoxyuridine. The samples were prepared 3 days later, when only 25 to 50% of the chromosome territories within nuclei are labeled. (The loss of labeling is determined by random segregation of the labeled and unlabeled chromatids.) Note that the DNA foci (d) are seen to cluster into discrete nuclear zones – these are chromosome territories – and that this zonal organization is much more distinct when the chromosome are labeled throughout S-phase (e). Though these samples are fixed prior to immunostaining the same observations can be made on living cells after introducing a fluorescent DNA precursor such as FITC-dUTP. (Reproduced from Jackson, D.A., Pombo, A. (1998) Replicon clusters are stable units of chromosome structure: evidence that nuclear organization contributes to the efficient activation and propagation of S-phase in human cells, *J. Cell Biol.* 140, 1285–1295 with permission of Rockefeller University Press. (f–g) show models for the proposed long and short-range architecture of chromosome territories. See Cremer, T., Cremer, C. (2001) Chromosome territories, nuclear architecture and gene regulation in mammalian cells, *Nat. Rev. Genet.* **2**, 292–301 for details. Image courtesy of Gregar Kreth and published with permission of Palgrave-Macmillan Publishing.) (See color plate p. xxx).

believed to reflect the transcriptional status of highly expressed gene-rich chromosomal regions. However, it remains to be established if the chromatin movement involved in the dynamic behavior of this type of chromatin loop reflects any functional association of specific genes with remote active centers – that is, specialized nuclear sites – which lie outside the territorial boundary.

The molecular interactions that define chromosome shape are not yet clear. Many lines of evidence suggest that an appropriate model to describe chromosome structure can be built around the random spatial distribution of DNA foci that contain roughly 1 Mb DNA (Fig. 7). Interestingly, structures of this size correlate with the replication foci, which, in early S-phase at least, correspond with local replicon clusters that are labeled together at specific times of the replication program. Even at the basic structural level this implies that structure and function must be related. How might this type of arrangement impact on chromatin function? In mammalian cells, it appears that the bulk of chromatin is only dynamic over short distances – perhaps ~0.5 μm or less. Beyond this, chromatin dynamics appear to be constrained by chromatin structure and numerous interactions that serve to tether chromatin to a variety of nuclear sites. Interestingly, in yeast, chromatin is so dynamic locally that a locus might move by as much as 0.5 μm during a period of only 10 s. Remarkably, this allows a single locus to pass through at least half of the nuclear volume in only 10 min. Such movements are known to be energy dependent, implying that they are probably related to nuclear activities such as replication or transcription.

3.6.1 Chromosome Structure

Chromosome structure must impose some form of order within chromosome territories and this is likely to influence function. It is generally assumed that the familiar rodlike appearance of metaphase chromosomes relies on the properties of a proteinaceous axis or core. It has been proposed that proteins within such a core might bind DNA to generate a chromosome with arrays of DNA loops of roughly 100 kbp. Simple staining techniques, using silver-based histological procedure, provide the most compelling evidence for an axial core structure, yet remarkably the proteins that might constitute this structure *in vivo* are not known. Isolated metaphase chromosome scaffolds have two predominant proteins – ScI and ScII – which for many years were the best candidates for the core. These are now known to be DNA topoisomerase IIα and SMC (structural maintenance of chromosomes) proteins. These proteins influence DNA topology and mitotic chromosome condensation and are essential for mitosis. However, studies on the behavior of these proteins in living cells do not support the idea that either topoisomerase or SMC proteins form a scaffold that organizes chromosome structure throughout the cell cycle. The likely explanation for this is that the observed structure reflects the complex biophysical properties of the nuclear components that remain associated with DNA throughout mitosis.

3.6.2 Functional Implications of Chromosome Structure and Location

Gene expression from ectopic (i.e. unnatural) chromosomal sites is extremely unpredictable. Genes introduced into inert chromosomal sites are generally inactive, though expression can be modulated by

the availability of heterochromatin proteins. Ectopic genes in active chromatin also behave unpredictably. For example, it is possible to analyze gene expression from artificial gene constructs introduced in predetermined target sites by homologous recombination. However, even when the chromosomal environment is controlled in this way, some genes display unpredictable patterns of ectopic expression, confirming that gene location at least has the potential to influence expression.

The expressional status of a gene can also be shown to influence its nuclear location. Studies on the lymphoid lineage of mammalian cells have shown that the inactivation of gene expression correlates with relocation of a gene to heterochromatic nuclear sites. During this process, the sequence-specific transcription factor Ikaros becomes associated both with the silenced gene and with local centromeric heterochromatin. Ikaros is able to bind both a target promoter and sites within the α-satellite repeats, so providing a means of driving appropriate genes into inactive heterochromatic sites. During B-lymphocyte development, the immunoglobulin H (IgH) and IgK loci are located at the nuclear periphery in hematopoietic progenitors and pro-T cells and in the nuclear interior in pro-B nuclei. The inactive loci are associated with the nuclear lamina and must move to active sites within the nuclear interior before recombination and transcription of the IgH and IgK loci can occur.

3.7 The Principles of Global Nuclear Structure

Thinking about the organization of major nuclear compartments such as nucleoli, the small nuclear bodies, sites of dedicated nuclear function – within factories – and chromosome territories leads us to assess the general principles that underlie nuclear architecture.

3.7.1 Organizing the Cytoplasm

A worthwhile way of approaching this issue is to first appreciate how major cellular activities are organized in the cytoplasm. As we have already seen, mammalian cells have a cytoplasmic compartment that is highly structured, with many membrane-bound organelles. But it is vital to recognize that this apparent structure belies the extremely dynamic nature of the cytoplasmic compartment. It is well known that membranes flow so that lipid bilayers can readily fuse one with the other. The use of GFP (green fluorescent protein), as a tool to study the dynamic behavior of various proteins of interest (each fused to GFP) in living cells, emphasizes this point. The dynamic properties of mitochondria provide an outstanding example: while an electron micrograph of a fixed mammalian cell might suggest that the cytoplasm contains numerous distinct mitochondria, live-cell studies show that these structures continually fuse with and bud from much larger mitochondrial networks. The endoplasmic reticulum, membranes of the Golgi apparatus, and membrane vesicles that lie downstream of the Golgi on the vesicle export pathways, each perform functions that require their components to be in a continual state of flux. However, while the observed intracellular activities might appear to be both dynamic and chaotic, they are in fact highly structured. Membrane-bound vesicles are too large to move inside the cytoplasm by diffusion, and move instead by energy-dependent processes that are directed by cytoplasmic motor proteins. The basic components needed to achieve this are the motor protein complexes themselves and a series of networks

upon which the motor proteins can move. In eukaryotes, the cytoskeleton provides the network that coordinates the movement and location of cytoplasmic vesicles and organelles.

Stated briefly for the sake of clarity, the cytoskeleton of higher eukaryotes is composed of three filamentous networks:

Microtubules (MTs) – are long hollow tubes that measure about 25 nm in diameter. They are composed of multimeric structures that are assembled from heterodimers of α- and β-tubulin. The tubules form with polarity, polymerizing and deploymerizing more rapidly at their + ends. The ends of MTs are usually embedded in a microtubule-organizing center. Typically, in higher cells, this will be the centrosome. MTs are dynamic, with a polymerization rate of $\sim$1 μm min^{-1}. However, MTs are stabilized through interactions with a large number of other proteins – the microtubule associate proteins (MAPs). During mitosis of the cell cycle, phosphorylation of MAPs by the cell cycle kinases has a dramatic impact on MT behavior; particularly with respect to their dynamic properties, which increase 5 to 10 fold. Under these circumstances, the MTs play a vital role in the process of chromosome segregation.

The MTs act as tracks for cytoplasmic motor proteins that fall into two broad classes. Generally speaking, kinesins are plus-end directed MT motor proteins and dyneins are minus-end directed MT motor proteins. Small families of each of these motors are known and these serve specific purposes and ensure that defined cargoes are able to move to appropriate sites throughout the cell.

Microfilaments (MFs) – are much narrower, typically about 8 nm across, helical polymers of a single protein, actin. Like the MTs a complex filamentous network of actin fibers pervades the cytoplasm of most eukaryotic cells. Like MTs, MFs are dynamic and serve as tracks upon which myosin motors can move organelles and vesicles around the cell. Actin filaments play particularly important roles in cell motility and cell architecture.

Intermediate filaments (IFs) – are a much more complex family of proteins that play particular roles in tissue architecture. As this role implies, the IF networks are much more important in multicellular eukaryotes than in their primitive ancestors; simple eukaryotes do not have intermediate filament proteins. IFs are $\sim$10 nm across and intermediate in size between MFs and MTs, hence the name. Members of the protein family have a distinct elongated central domain that interacts as a coiled-coil structure to generate first dimers and then complex multimers that form the filaments. The family in mammals has about 50 members, though different members are expressed in a cell lineage–dependent manner. Keratins, for example, are expressed in the epidermis of the skin and play a vital role in maintaining the mechanical properties of this organ.

Cytoskeleton – is the structure formed from these three networks. The networks are closely associated and cross-linked, through the behavior of associated proteins so that the function of each is dependent on the structure of the others. The cytoskeleton should be considered as an integrated network with cooperative functions.

Even a superficial appraisal of cytoplasmic architecture begs the question: do the essential functions performed by the cytoskeleton have counterparts in the nucleus and if so do any analogous structures exist? This question has been a focus of intense debate over the past 25 years. We have already discussed the function and properties of the nuclear lamina. This network of type V intermediate filament

proteins is by far the best-characterized structural nuclear network. Roles played at the nuclear periphery are particularly clear. What remains more a matter of speculation is whether a diffuse lamin network spreads throughout the nucleoplasm, and if this could then support the nuclear functions that many investigators believe take place at a nuclear matrix.

3.7.2 The Nuclear Matrix – Fact or Fiction

This leads us to assess what the nuclear matrix might be and analyze the functions it might perform. We have seen that nuclei can be plastic, so that they appear to have a complex structure of nuclear compartments, which generally represent centers of nuclear function. These centers have components that are inherently dynamic and in general are not stable entities – this is self-evident given that most are disrupted during mitosis. However, while these compartments might be plastic, it is also interesting to note that the spatial organization of sites such as transcription and replication factories and nuclear speckles is unaffected if nuclei are depleted of chromatin (Fig. 8). This suggests that the compartments are spatially constrained and raises the possibility that a ''solid phase'' exists within nuclei to provide a platform upon which the active sites assemble. A ''nucleoskeleton'' has been proposed to fulfil his role.

The nature of the nucleoskeleton and related nuclear matrix remains a matter of debate. Core filaments that could provide a form of continuity throughout the nuclei have been described. These filaments have characteristic morphological features of the intermediate filaments seen throughout the cytoplasm. The best-characterized intermediate filaments within nuclei are undoubtedly the nuclear lamins. However, in addition to roles played by the nuclear lamins at the nuclear periphery, recent studies using GFP-lamin proteins and classical high-resolution immunostaining have suggested that a veil of lamin filaments spreads throughout the nucleus. These observations support the idea that a lamin-based network might pervade the nucleoplasm to provide a framework to coordinate the organization of various nuclear compartments. This idea, however, remains controversial and it is still a matter of debate as to whether the lamins might form a contiguous internal nucleoskeleton. As an alternative, the lamins could feasibly play a structural role in the short-range organization of nuclear compartments such as transcription centers.

3.7.3 Proteins of the Nuclear Matrix

The nuclear matrix is classically described as an amorphous fibrogranular structure that can be isolated from the nuclei by hypertonic treatment following nuclease digestion. By this definition the matrix is perceived as being a product of the nucleoskeleton/nuclear lamina networks and associated proteins. The matrix typically contains many hundreds of different proteins, many of which have been studied in detail. Two of the best characterized – SAF-A (scaffold attachment factor A) and ARBP (attachment region binding protein) – were discovered because of their association with the matrix attached DNA elements. SAF-A turns out to be a major RNA binding protein (hnRNP-U) and ARBP is a protein that binds methylated DNA (MeCP2). SAF-A has been shown to bind p300, a major transcriptional coactivator, and so recruit active genes to the nuclear matrix. ARBP, in contrast, interacts with methylated DNA in MAR elements and through an intermediary that contains Sin3A protein recruits histone deacetylases to generate

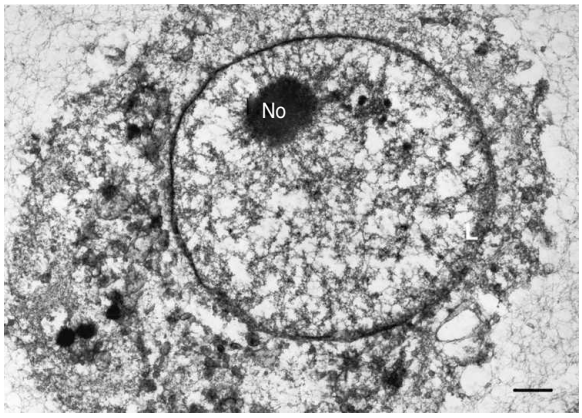

Fig. 8 Nuclear architecture and the nucleoskeleton. To reveal the nucleoskeleton, HeLa cells encapsulated in agarose microbeads were permeabilized and chromatin cut with nucleases so that ~90% DNA could be removed before preparing a resinless electron micrograph. In this ~250-nm thick section, note that a diffuse agarose mesh surrounds the densely stained cell. The spherical, central nucleus is demarcated by a dense nuclear lamina (L). Critically, in this example, nuclear architecture is preserved even though most chromatin – half of the nuclear mass – is removed. The residual nucleoskeleton can be visualized as a diffuse network of coated filaments that pervade the nuclear volume and provide a ''solid phase'' upon which nuclear compartments such as nucleoli (No), replication and transcription factories and interchromatin granule clusters are assembled. Note that the distribution of transcription and replication centers is preserved even though almost all chromatin has been removed. The bar is 2 μm. (Reproduced from Hozak, P., Jackson, D.A., Cook, P.R. (1994) Replication factories and nuclear bodies: the ultrastructural characterization of replication sites during the cell cycle, *J. Cell Sci.* **107**, 2191–2202. With permission of the Company of Biologists.)

a silenced chromatin state. Another protein, SAF-B, (scaffold attachment factor B) specifically binds to S/MAR regions, interacts with RNA polymerase II (RNA pol II) and a subset of serine-/arginine-rich RNA processing factors (SR proteins). It was proposed that these interactions allow SAF-B to provide a surface for the assembly of the transcription apparatus. As with the vast majority of characterized matrix proteins, these are involved in different aspects of chromatin function. Extending this idea implies that the nucleoskeleton and nuclear matrix (that forms during salt extraction) are an expression of different processes that are performed within the interchromatin space.

Recent studies on the nuclear matrix protein SATB1 (special AT-rich sequence binding 1) emphasize this view. SATB1 is a nuclear matrix component that is found predominantly in thymocytes. In these cells, a nuclear network of SATB1 binds chromatin to form chromatin domains

that are believed to play important roles in gene regulation. SATB1 in association with MARs acts as a transcriptional repressor to regulate gene expression during T-cell development. This protein has the classical properties of a nuclear matrix component and deletion of SATB1 results in defects in the temporal and spatial regulation of many lymphocyte genes, leading to an arrest of T-cell development. SATB1 is known to target chromatin remodeling factors to specific chromatin domains and so provide a mechanism for the long-range regulation of gene expression. SATB1 recruits histone deacetylase complexes containing the NURD chromatin remodeling complex to SATB1-bound sites in the interleukin-2 receptor gene to elicit specific deacetylation of histones within the locus. In addition, SATB1 was shown to target CHRAC and ACF chromatin remodeling complexes to regulate nucleosome positioning over several kbp DNA. SATB1 might also play a direct role in recruiting RNA polymerase II to specific nuclear sites.

3.7.4 Functions at the Matrix

Numerous experiments support the existence of a nuclear matrix that plays central roles in nuclear function. An excellent example is provided by the studies of the behavior of the runt-related transcription factors (RUNX/CBFA/AML), which play essential roles in cellular differentiation and fetal development. A domain within the RUNX transcriptional activators targets the protein to discrete subnuclear foci. Removal of the targeting domain results in lethal hematopoietic and skeletal phenotypes, and implies that for this class of protein the correct nuclear location is critical for the function. The behavior of GFP-RUNX fusion proteins in living cells confirms that RUNX proteins occupy discrete nuclear foci, the majority of which are coincident with transcription sites and associated with a low-salt nuclear matrix. RUNX proteins also interact with Smads, a family of signaling proteins that regulate various developmental and biological processes in response to growth factors. Interestingly, the RUNX proteins are required to target Smads to nuclear sites where transcription is performed. This implies that gene expression involves the *in situ* integration of critical signals through the assembly of regulatory complexes at transcriptionally active subnuclear sites. This work and other studies suggest that activating factors engage appropriate nuclear sites that are competent to perform gene expression and that the process of transcription can only occur once a gene has been recruited to the active center.

4 Integrating Nuclear Structure and Function

Having addressed different aspects of nuclear structure and function we should now explore how these might be integrated and assess if this process influences our perceptions of nuclear organization. The basic principles of chromosome territory organization were outlined earlier. However, it is important to remember that these territories are not homogeneous structures. It is possible, for example, to use three-dimensional FISH techniques to show that condensed chromatin as well as the active chromatin compartment (using specific antibodies for modified histones found in transcribed chromatin) occupy spatially distinct compartments from the transcription factor TFIIH, RNA polymerase II, and hnRNP-U. Interestingly, these proteins are present throughout the

interchromatin space, inside each territory and largely excluded from the domains of chromatin. This approach and other high-resolution studies support the view that transcription centers are restricted to the RNA-rich interchromatin compartment. This interchromatin compartment supports all the major chromatin functions – and it is within this compartment that any nuclear matrix must form.

4.1 Chromatin Structure and Function

While appreciating that the way nuclei are organized might have a profound impact on nuclear function, it is also important to understand how DNA is organized in order to provide an amenable template that supports the major functions. In this respect, it is necessary to understand how DNA is packaged as chromatin and how the properties of this DNA–protein complex impact on function.

To emphasize this point, it is well known that different genes are expressed to quite different extents and that many are expressed in specific cells and at precise times during development. This begs the question: how are different levels of gene expression maintained? For a specific gene, chromatin status and the availability of activating transcription factors will combine to establish an engaged transcription complex that drives RNA synthesis. The role of chromatin structure is clearly implicit in the success of this process. It has been know for many years that active and inactive genes have quite distinct chromatin states and that inert chromatin is able to spread – and so downregulate the previously active genes. Two general features are fundamental in protecting the functional status of the active genes. The first concerns the maintenance of a fluid and active chromatin state through histone modification. The second requires that genes are organized into chromatin domains that behave as the functional units of gene expression. The structure of these domains, at least within the confines of their natural chromosomal locus, might ensure that genes are expressed at the desired levels in appropriate tissues and at the required times during development.

4.1.1 Chromatin Function

Work that determined the genetic code that defines humanity represents a landmark of scientific endeavor. But with this treasure comes the realization that it will not always be possible to decode information held within the genome in a way that might allow us to predict patterns and levels of gene expression in different cell types and at different stages of their development. Some aspects of gene expression control are genetic in origin. Most notably, we have seen how gene expression is activated when transcription factors interact with their cognate recognition motifs in gene promoters and other activating sequences – such as enhancers – to form a complex that recruits the transcription machinery to a gene. This process of sequence-dependent association of specific proteins with defined sequence elements within DNA can be studied in molecular detail, and is conceptually simple to understand. In higher eukaryotes, in particular, these genetic controls are supplemented by a variety of ''epigenetic'' factors that modulate chromatin structure and both chromosome and nuclear architecture.

4.1.2 DNA Packaging and Chromatin

Somatic mammalian cells are usually diploid; they contain two sets of

chromosomes one inherited from each of the two parents. Humans have 46 chromosomes with about 6×10^9 bp DNA in total. The structure of DNA, with its acid sugar-phosphate backbone, demands that some mechanism must have evolved to neutralize the negatively charged phosphate groups in order to fold DNA so that it might fit inside a mammalian nucleus. Note that this amount of DNA would cover about 2 m if extended, yet must fold to occupy a nucleus that is only ~10 μm in diameter. A family of small (about 10 kDa) arginine and lysine-rich proteins called *histones* are responsible for DNA packaging. The fundamental structural unit of DNA packaging is called the *nucleosome*. The core structure of a nucleosome (Fig. 9) contains ~146 bp DNA wrapped as 1.75 turns over the surface of a histone octamer. The protein core structure contains two sets of the four core histones – called *histones* H2A, H2B, H3 and H4 – arranged with mirror symmetry around the dyad axis of the nucleosome. The histone genes themselves are extremely highly conserved throughout eukaryotes as their proteins must interact in a very precise way to form the nucleosome core. The core structure is in turn defined by the architecture of the individual histone proteins (Fig. 9) while

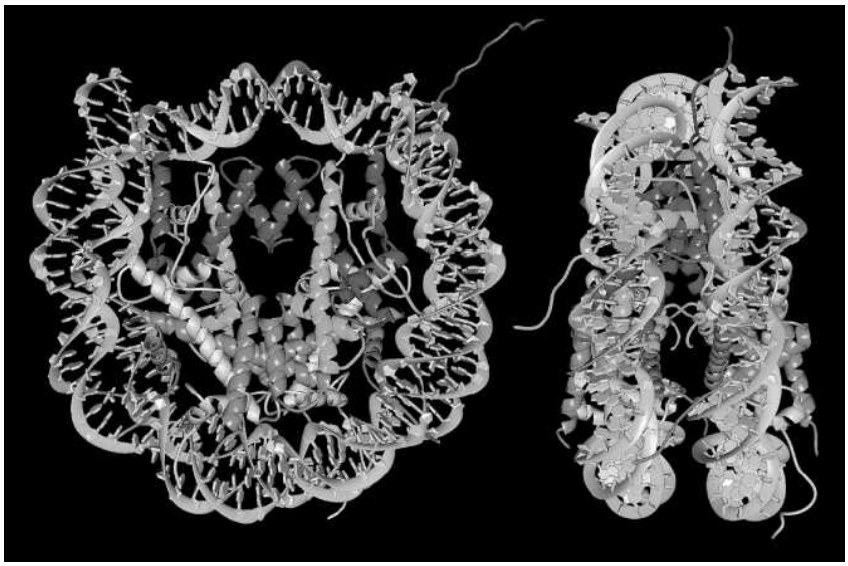

Fig. 9 The nucleosome. High-resolution X-ray crystal analysis can be used to demonstrate the structure of a nucleosome. In this nucleosome core particle, 146 bp of DNA (turquoise and brown) wraps ~1.75 times around the histone octamer. The octamer of each core contains two molecules each of histones H2A (yellow), H2B (red), H3 (blue) and H4 (green). Each of the core histones has a central domain with three α-helical regions separated by short coils. Interactions between these domains within the core determine the core structure. The N-terminal domains are unstructured and can extend to the outside surface of the nucleosome. The dimensions of this core structure are 10×6 nm. (Reproduced from Luger, K., Mader, A.W., Richmond, R.K., Sargent, D.F., Richmond, T.J. (1997) Crystal structure of the nucleosome core particle at 2.8 angstrom resolution, *Nature* **389**, 251–260. With permission of Palgrave-Macmillan Publishing.) (See color plate p. xxxi).

the N-terminal domains of the histones associate with DNA and allow interaction between adjacent nucleosomes.

4.1.3 Euchromatin and Heterochromatin

As the chromatin fiber is the template for functions such as DNA replication and RNA transcription, the importance of this DNA–protein complex cannot be overstated. In particular, it is crucial to recognize how modification of chromatin structure impacts on the behavior of chromatin. Broadly speaking, chromatin within a mammalian nucleus can be characterized as euchromatin or heterochromatin. The former is ostensibly composed of chromosomal regions that have a high density of transcriptionally active genes. Euchromatin corresponds to chromosomal regions that can be classified as R-bands using cytological criteria. These are slightly GC-rich (because of GC-islands associated with housekeeping genes), have a high density of Alu-repeats and are duplicated in the early part of S-phase. Heterochromatin, in contrast, has many fewer transcribed genes, occupies chromosomal G- and C-bands and is replicated in the second half of S-phase. Euchromatin and heterochromatin have distinct features that correlate with these characteristics. Perhaps the most diagnostic among these is the ease with which the different chromatin populations can be cut with nucleases. Hence, euchromatin is readily digested with enzymes such as DNase – it is classified as being DNase sensitive – whereas heterochromatin is relatively insensitive. This ease of digestion reflects the accessibility of DNA to DNAse – euchromatin has a loose or open chromatin structure, whereas heterochromatin is more compact. These basic chromatin states correlate with a functional status, which reflects how transcribed genes are packed into chromatin that is modified to allow transcription to occur.

4.1.4 Histone Modifications

As chromatin modification is central to the control of gene expression, it is important to understand at least the basic principles of this process. It has been known for many years that the histones are subject to a wide range of modifications. These include acetylation, methylation, phosphorylation, ADP-ribosylation, and ubiquination. These modifications are used to generate and stabilize the different classes of chromatin, modulate chromatin structure throughout the cell cycle, and control histone turnover. In terms of gene expression, acetylation of the N-terminal domains of histones – particularly H3 and H4 – is of the greatest importance. These lysine-rich domains each have numerous lysine residues that are targets for acetylation. Acetylation serves to reduce the stability of the nucleosome complex so that the DNA is more readily accessible to the transcription machinery.

The mechanisms by which histone acetylation are controlled are extremely complex. Levels of acetylation at any locus are dictated by the combined activities of histone acetyl transferases (HATs) and histone deacetylase complexes (HDACs). The activity of these large protein complexes is determined, in turn, by mechanisms that control their recruitment to different nuclear sites. The protein p300/CBP is a global transcriptional regulator that binds to enhancers within many gene loci and contains a HAT activity that is capable of acetylating specific sites in all the core histones and other transcription factors to stimulate transcription. In addition, complexes such as PCAF interact with p300/CBP, SCR1/ACTR and

other DNA-binding activators to stimulate transcription by histone acetylation, predominantly in histone H3. Components of the multi-subunit general transcription factors TFIID and TFIIIC also have HAT activities that modify histones H3 and H4 to stimulate transcription and other HAT activities are associated with the elongating polymerase holoenzyme complexes. The patterns of histone acetylation that might be developed in response to these different activities can be extremely complex; different HATs have numerous potential acetylation targets and different preferences for the various sites. Major modifications that correlate with an active chromatin status include acetylation of histone H3 at lysines 9 and 14 and H4 at lysine 5. Specificity for particular sites in chromatin is a product of the mechanisms of association of each HAT with chromatin. The bromodomain of these proteins is thought to play a role in this process.

Histone acetylation in euchromatin correlates with gene activity. In contrast, inactive, heterochromatin has lower levels of acetylation and much higher levels of histone methylation and phosphorylation. The human suppressor of variegation protein SUV39H1 encodes a histone methyltransferase (HMT) that selectively methylates histone H3 at lysine 9. This activity is dependent on a SET domain within the protein. This particular histone modification induces high-affinity binding of the heterochromatin protein HP1, through chromodomains. The other major group of heterochromatin proteins, the polycomb group (Pc-G) proteins, are known to recruit protein complexes with histone deacetylase activity. Pc-G proteins and antagonizing proteins of the trithorax group (trx-G) together play a fundamental role in modulating the dynamic transition between inactive and active chromatin states.

4.1.5 **ATP-dependent Chromatin Remodeling Machines**

Chromatin status and the activity of complexes that catalyze the modification of the histones are also influenced by the activity of a variety of protein complexes that perform ATP-dependent chromatin remodeling. These complexes were first described in studies to understand the control of mating type switching (SWI) and sucrose fermentation (SNF for sucrose nonfermenting) in yeast. Chromatin remodeling was recognized as a major factor in these two processes and has since been shown to be a fundamental regulator of gene expression. Examples of the remodeling machines in human cells include the human SWI/SNF complex, NURD (nucleosome remodeling histone deacetylase complex) and RSF (remodeling and spacing factor). These multiprotein complexes operate through different chromatin binding domains. hSWI/SNF has a bromodomain, NURD chromodomains and RSF a SANT domain.

These chromatin remodeling machines serve to increase the local dynamic properties of chromatin. DNA and histones in chromatin make so many contacts that the nucleosomes they form are inherently stable structures. Nucleosomes can form on almost all stretches of DNA of sufficient length, though the need to fold the DNA duplex over the nucleosome surface does impose constraints on the way chromatin forms. In particular, the center of the dyad axis in a nucleosome has a region of DNA that is distorted or kinked in order to make the necessary contacts with the histones of the nucleosome core. AT bases in DNA are preferred at this location. Other mechanisms exist to position the nucleosome in a specific way – the binding of a factor with DNA prior to establishing local chromatin structure would be an

obvious mechanism. The ATP-dependent chromatin remodeling activities serve to enhance the fluid properties of nucleosomes; in essence, they allow nucleosomes to slide on DNA. The mechanism of this process is not known in detail, but is assumed to reduce the activation energy needed to reposition a nucleosome core.

Hence, the chromatin remodeling machines provide a means by which nucleosomes can be repositioned to allow access to previous inaccessible sites in DNA. This activity will function cooperatively with the histone modification systems described above to modulate and stabilize different chromatin states. The combination of these activities adds a huge complexity to the epigenetic control of chromatin function. Indeed, present estimates suggest that something in the region of 50 chromatin-modifying complexes will collaborate to ensure that chromatin is an extremely complex and structurally dynamic substrate.

4.2 Higher-order Chromatin Folding

The following section touches briefly on chromatin architecture and in particular, on differences in chromatin structure that correlate with chromatin function, notably RNA transcription. With this in mind, it is worth emphasizing that only a very small fraction – about 1% – of the DNA within a mammalian cell is represented by messenger RNA (mRNA) that is decoded to generate proteins in the cytoplasm. About 10 to 20% of the DNA is in the euchromatin that is transcribed to generate the primary transcripts – called *heterogeneous RNA (hnRNA)* – that are subsequently processed to form mature mRNAs. Individual cell types have distinct expression profiles that are determined by their developmental history (differentiation program). About one-third of the roughly 35 000 genes of human cells are housekeeping genes that are expressed in all cell types. The others are expressed in specific, specialized cell types and generally form facultative heterochromatin in cells in which they are not expressed and euchromatin in cells in which they are expressed.

It is self-evident that DNA must be highly folded so as to accommodate 2 m of DNA in a nucleus measuring only 10 μm in diameter (Fig. 10). The wrapping of DNA around the nucleosome core begins the condensation process that is continued by a hierarchy of higher-order DNA folding. Nucleosomal chromatin can be visualized by electron microscopy, as a chromatin fiber of beads on a string; in which each bead or nucleosome is separated from the next by a short stretch of intervening linker DNA; in mammalian cells these linkers are typically 50 to 100 bp in length. As nucleosomes are 10 nm in diameter, this is referred to as the 10-nm chromatin fiber. Inside the cell, euchromatin is loosely folded as a locally chaotic 10-nm chromatin fiber. Interactions between different regions of the fiber might generate local variations in chromatin density – though generally the chromatin will appear diffuse. Heterochromatin, in contrast, is much more highly compacted.

When chromatin is visualized in thin sections of mammalian cells a number of folded forms can be identified. Aggregates of the 10-nm fiber form a fiber with an average diameter of ~30 nm. Historically, a chromatin fiber of this size has been referred to as the chromatin solenoid – in which six nucleosomes are held in one turn of the solenoid by histone H1. Histone H1 is known as a linker histone; it is much richer in heterochromatin, with about 1 copy per nucleosome core compared to

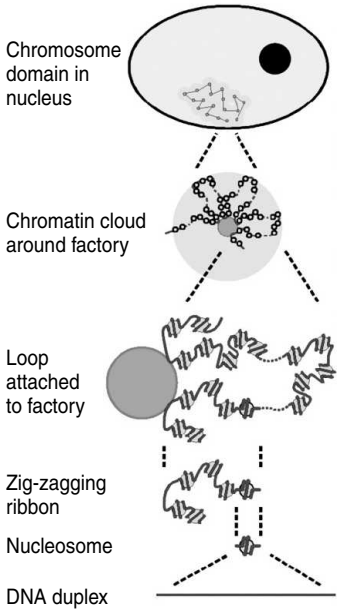

Fig. 10 Chromatin folding. The DNA within a mammalian nucleus is highly folded. The required folding is achieved first by wrapping DNA around the surface of histone complexes to form nucleosomes. Long stretches of nucleosomes then fold to form the higher-order chromatin structures. In the model shown here, DNA foci – see Figure 7 – are depicted as the critical architectural units of higher-order packaging. It is not certain how these structures are formed, but one possibility is that DNA loops are arrayed as stable entities in a way that reflects their functional status at sites of RNA and DNA synthesis. In this example, a cluster of chromatin loops is arrayed around a transcription factory. Within this type of higher-order structure, chromatin might be either open, as euchromatin or more condensed, as heterochromatin. These chromatin states correlate with various histone modifications that either allow chromatin to be transcribed or stimulate local aggregation of the chromatin clouds. (Reproduced from Cook, P.R. (2001) *The Principles of Nuclear Structure and Function*, John Wiley and Sons, New York with permission of John Wiley and Sons.)

about 0.5 copies per nucleosome core in DNase sensitive euchromatin. The solenoid represents the second level of chromatin folding. This structure is not thought to fold according to specific design parameters, however, and is more probably best imagined as a short-range chromatin aggregate that is stabilized by association with chromatin proteins such as histone H1. Further condensation of the chromatin leads to the formation of condensed fibers with diameters in the range of 50 to 80 nm. These are typical of the structures seen in heterochromatin during the interphase and are stabilized by association with heterochromatin proteins such as HP1 and Pc-G proteins. The most highly condensed chromatin fibers are found in mitotic chromosomes where histone modifications that result from the activity of the mitotic cdc/cyclin complexes yield chromatin fibers of 150 to 200 nm. These are folded around the axis of the chromatids, which have an overall diameter of about 600 nm.

4.2.1 Chromatin Domains and Loops

Interactions that allow the stabilization and modulation of chromatin status will clearly have a profound impact on chromatin organization within the nuclei of higher eukaryotes. However, these do not seem to be the only aspects of

chromatin organization that dictate how chromatin is packaged *in vivo*. An important consideration here is the way genes might be organized into chromatin domains – these are usually conceptualized as DNA loops – that might be regarded as the structural units of gene expression.

Evidence for the existence of discrete chromatin domains comes from a number of sources. Nucleases sensitivity is the classical indicator of chromatin structures that correlates with gene expression; general nuclease sensitivity of active loci will often spread throughout domains that cover many kbp up- and downstream of an expressed gene. Chromatin immunoprecipitation experiments – using antibodies to histone variants found in active chromatin – confirm this. Moreover, clear transitions from active to inactive chromatin suggest that chromatin domains are demarcated by elements that determine the boundaries of functional genetic units. As an example, consider a high-resolution analysis of acetylation across three genes in the vicinity of the chicken β-globin locus. This chromosomal region contains a folate receptor gene, a 16-kbp condensed chromatin region, the β-globin gene domain and an adjacent olfactory receptor gene. The condensed chromatin maintains very low levels of histone acetylation at all developmental stages, with similar levels maintained in inactive genes. Much higher levels of acetylation are seen throughout the transcribed gene domains, while chromatin in the vicinity of upstream regulatory sites maintain the highest levels of acetylation. Most significantly, a very strong constitutive focus of hyperacetylation corresponds with an insulator element that appears to define the globin and adjacent folate receptor domains. These observations show how epigenetic modifications influence the chromatin domain structure and also imply that different classes of histone acetyl transferase with different chromatin targets are involved in the control of gene expression.

Various genetic elements have been described that together define the structure of chromatin domains and regulate gene expression. These include: promoter elements, enhancers, LCRs, S/MARs and insulators. Enhancers and LCRs generally contain arrays of transcription factor binding sites that bind appropriate factors to augment levels of gene expression, by directly upregulating rates of transcription. These components contribute to the maintenance of a gene's expressional status and are responsible for establishing a productive spatial configuration in chromatin and perhaps for targeting chromatin to specific nuclear sites. In some cases, LCRs are required to establish natural levels of gene expression from ectopic (unnatural) chromosomal sites.

The nuclear matrix and related scaffold are believed to play important roles in different aspects of chromatin function. S/MARs are DNA elements that clearly augment transcription and may achieve this using AT-rich sequences to modulate superhelical stress that arises during transcription. The importance of these elements in gene regulation is confirmed by the fact that a classical MAR element is known to play a critical role in orchestrating the temporal and spatial expression of many genes during T-cell development. In addition to this, efficient MAR elements have been shown to support long-term gene expression from ectopic chromosomal sites, suggesting that these elements might play a role in targeting gene domains to specific nuclear sites, such as matrix-associated transcription centers, prior to gene expression. These elements are probably distinct from

insulators, which are believed to function as chromatin domain boundaries that generate self-contained units of gene expression.

The combined action of promoter, enhancer, S/MAR and insulator elements will together dictate levels of gene expression. In addition, through their interaction with proteins involved in gene expression, these elements will play an important part in determining how DNA is organized and packaged within the nuclear space.

5 Overview

This chapter sets out to give the reader an overview of our present understanding of the nuclear structure and function. The majority of examples have been drawn from studies on mammalian cells. This was a deliberate choice, as even though many critical advances have been made using simple model systems, the added complexity of mammalian genomes makes them a much more challenging object of study. As the area covered herein represents an extensive field of research, it is inevitable that the treatment of many has been superficial. This should not be seen to reflect my own view of the relative importance of different topics. Instead, I have attempted to deliver a coherent appraisal of this cell organelle with the intention of stimulating interest in the reader so that he or she will feel encouraged to look deeper into this fascinating subject.

In discussing the nucleus, the main focus of attention must be the structure and function of DNA. Little attention is paid to the DNA itself, though the way DNA is packaged in nuclei undoubtedly has a profound influence on chromatin function. The structure of chromatin and more importantly the cellular mechanisms that modulate chromatin fluidity and hence control access of DNA to RNA and DNA polymerases are now well known. Indeed, histone modifications represent a major source of epigenetic information that complements the genetic information defined by DNA sequence. Chromosome structure and global nuclear architecture provide additional sources of epigenetic information, which at least have the potential to influence chromatin function. However, while many specific examples have been reported to show how chromosome and/or nuclear location influence chromatin function, the relative importance of this type of spatial epigenetics remains largely unexplored. Whatever the hierarchies of control turn out to be, there is no denying that the structure of mammalian nuclei and the functions that they perform are very sophisticated indeed.

Keywords

Hematopoietic Stem Cell (HSC)
A pluripotent cell that gives rise to all of the blood lineages and has the ability to undergo self-renewal.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.
Copyright © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim.
ISBN: 3-527-30544-0

Hematopoietic Progenitor
Unipotent or multipotent cells that give rise to committed blood precursors that in turn develop into fully differentiated blood cells.

Primitive Hematopoiesis
The first wave of hematopoiesis that occurs during development that generates large numbers of primitive erythrocytes and some primitive leukocytes.

Definitive Hematopoiesis
The hematopoiesis that permanently replaces primitive hematopoiesis during fetal stages to supply all fetal and adult blood lineages.

Primitive hematopoiesis is the first wave of blood development that occurs in development, and it produces the first red and white blood cells of the embryo. Although primitive hematopoiesis produces a largely transient population of primitive blood cells, some blood progenitors that function later in development to produce definitive blood cells also develop in the primitive hematopoietic site. Studies of mouse, chick, zebrafish, and *Xenopus* embryos have revealed that many of the molecular events that regulate primitive hematopoiesis are conserved among vertebrates. In addition, roles for nonhematopoietic tissues in regulating primitive hematopoiesis have been discovered. In this article, we review what is known about vertebrate primitive hematopoiesis at the tissue, cellular, and molecular levels.

1 Primitive Hematopoiesis

Hematopoiesis is the generation of blood cells (erythrocytes and leukocytes) from a common precursor, the hematopoietic stem cell (HSC). During development, two types of hematopoiesis, primitive and definitive, supply the embryo with blood cells (Fig. 1). The first wave of hematopoiesis is termed primitive because it produces blood cells that are primitive in character in that they do not fully resemble their adult counterparts either functionally or molecularly. Primitive blood cells exist transiently, primarily serving the embryo's early requirement for oxygen, until the second and final wave of hematopoiesis, definitive hematopoiesis, occurs. Definitive hematopoiesis continuously produces all the fetal and adult blood lineages, including the myeloid (red cells, macrophages neutrophils, mast cells, platelets) and lymphoid (B-cells and T-cells) lineages throughout the life of the animal. Although there are anatomical differences in where both waves of hematopoiesis occur among vertebrate species, there is a striking conservation of the genes required for these processes.

The most numerous cells generated during primitive hematopoiesis are primitive erythrocytes, large nucleated cells that express embryonic globins and accumulate

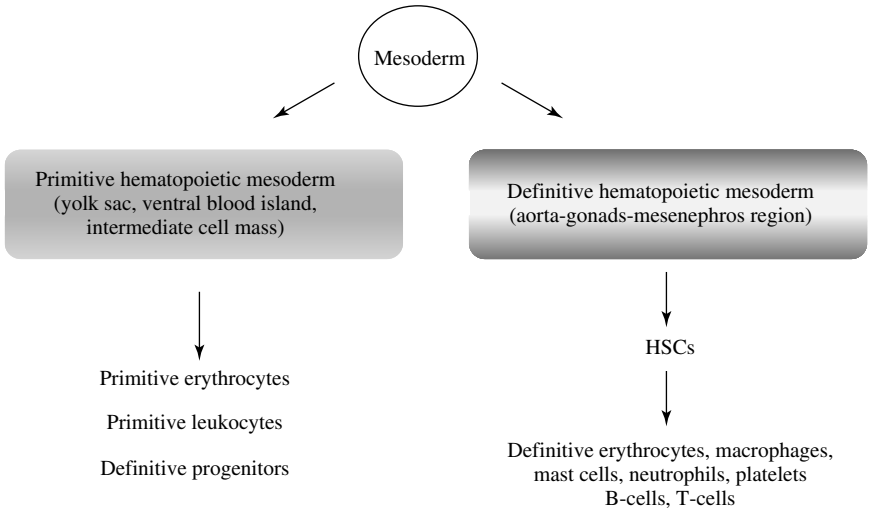

Fig. 1 Embryonic hematopoiesis. This simplified illustration depicts the differentiated cell types that are produced during the first waves of primitive and definitive hematopoiesis, respectively. There are many steps and intermediate cell types in these pathways that are discussed within the text.

hemoglobin during maturation. In contrast, definitive erythrocytes are smaller, contain fetal or adult globins and are enucleated (e.g. in mammals) or have different nuclear morphology (e.g. in *Xenopus*). In all vertebrates, primitive hematopoiesis is initiated during gastrulation in the embryonic or extraembryonic mesoderm, depending upon the species. In mammals and birds, primitive hematopoiesis occurs extraembryonically within the yolk sac mesoderm, whereas in *Xenopus* (African clawed frog) and zebrafish, primitive hematopoiesis occurs embryonically, in a subset of ventrolateral mesoderm known as the *ventral blood islands* and *intermediate cell mass*, respectively. In the mouse, nonhemoglobinized primitive erythroblasts (immature primitive erythrocytes) are first morphologically evident during late gastrulation stages, around embryonic day (E) 7.5 in the yolk sac mesoderm, and they enter the embryo via the circulatory system at E8.25. After E9, primitive erythroid cells are no longer produced by the yolk sac. Within the embryonic blood vessels, primitive erythroid progenitors complete their differentiation in circulation through E13, undergoing mitosis, nuclear condensation, accruement of hemoglobin, and a decrease in cell size. Prior to E12 in the mouse, the only red cells in circulation are derived from the yolk sac. At E12, some liver-derived definitive erythroblasts (that are smaller in size and express adult globins) enter circulation, and within a few days, the primitive erythrocytes are no longer detectable. In the chick, yolk sac mesoderm differentiates into primitive erythroblasts by 1.5 days postfertilization and the erythroblasts enter circulation by day 2, and subsequently mature. In *Xenopus*, ventral blood island-derived primitive erythrocytes enter circulation at stage 35/36, just a few hours after the heart starts beating, and they are the predominant circulating cells until they are replaced by definitive erythrocytes

after metamorphosis. Zebrafish primitive erythroblasts are produced in a synchronous wave in the lateral mesoderm and are morphologically detectable within the intermediate cell mass at 20 hours postfertilization (hpf). Subsequently, they enter embryonic circulation around 24 hpf, where they complete maturation around 5 days postfertilization (dpf). Until 4 dpf, primitive erythrocytes are the only red cells in the blood stream; definitive cells begin to circulate at 5 dpf.

Although primitive hematopoiesis is often defined as the production of primitive erythrocytes, primitive leukocytes are also generated in some species. The exact *in vivo* function of primitive leukocytes has not been well characterized, however. In the mouse, megakaryocyte progenitors are detectable in cultured E7.5 yolk sac cells and primitive megakaryocytes are evident in the yolk sac of intact embryos at E8.5. Primitive megakaryocytes differ significantly from their definitive counterparts by their smaller size, rapid differentiation kinetics, chromosome number, and response to cytokines *in vitro*. It has been suggested that primitive megakaryocytes play a role in maintaining early blood vessel integrity through production of platelets, but this possibility remains to be tested. It is not known whether other vertebrates also produce primitive megakaryocytes. Primitive macrophages are found in all vertebrates and differ significantly from definitive macrophages in many ways, including their phagocytic activity. Electron microscopic studies of the mouse embryo demonstrated the presence of macrophage cells in the yolk sac at E7. Macrophage progenitors are detected in early mouse embryos at the same time and place that primitive erythroid progenitors are first detected, suggesting that the yolk sac is also a source of macrophage progenitors. In *Xenopus*, the ventral blood island gives rise to circulating macrophages but a larger, nonventral blood island–derived macrophage population originates from a region anterior to the heart and migrates interstitially throughout the mesenchyme of the larval body. Recently, it was demonstrated that in zebrafish, a similar population of migrating macrophages develop from a site anterior to the primitive erythroid site. Presumably, macrophages that develop during primitive hematopoiesis function to remove dead cells from the embryo and are involved in tissue remodeling. In summary, although primitive hematopoiesis mostly contributes primitive erythrocytes, it also yields a number of non-erythroid myeloid cells. Further characterization of these primitive myeloid populations will reveal their functions in the early embryo.

Although multiple primitive blood lineages are detected in some vertebrate species, there is no experimental evidence demonstrating that primitive blood cells are derived from HSCs. Markers that uniquely identify HSCs are currently not known; therefore, HSCs are experimentally defined as self-renewing cells that can provide long-term hematopoietic reconstitution of an adult host. Specifically, embryonic HSCs are detected by dissociating embryos or embryo fragments into single cells and transplanting these cells into adults that typically lack their own functional hematopoietic system because they have been irradiated or they carry genetic mutations that impair normal hematopoiesis. If the transplanted embryonic cells contain HSCs, and these HSCs can home to and engraft sites that support hematopoiesis, blood lineages are reconstituted and long-term survival is achieved because the embryo-derived HSCs can self-renew and continuously supply blood

lineage progenitors. In species in which such assays are possible, HSCs are not detected prior to the emergence of primitive progenitors. It is presently unclear, however, whether the inability to detect primitive HSCs is because of experimental limitations or because they simply do not exist.

In addition to primitive erythroid and primitive myeloid progenitors, primitive hematopoietic tissue has also been demonstrated to give rise to definitive progenitors and possibly some definitive HSCs in a species-specific manner. The relationship between primitive hematopoiesis and definitive HSCs in the developing vertebrate embryo, particularly in the mouse, is somewhat contentious. Of some controversy is whether HSCs with definitive potential produced in primitive hematopoietic sites contribute to definitive hematopoiesis *in vivo* or if HSCs with definitive potential are produced *de novo* in the embryo, at sites where primitive hematopoiesis does not occur. Historically, researchers believed that the yolk sac gives rise to HSCs that subsequently seed the embryonic sites of definitive hematopoiesis, the aorta-gonads-mesonephros region and liver, and thus give rise to all definitive lineages. This belief was supported by the observation that hematopoietic cells emerge first in the yolk sac and then later in the liver during embryogenesis. Moreover, it was shown that cultured embryos lacking yolk sacs fail to carry out definitive hematopoiesis. Two subsequent experimental approaches seriously challenged this conclusion. First, it was shown that transplanting quail embryos onto stage-matched precirculatory yolk sacs (Hamburger-Hamilton [HH] stage 9) from chick embryos and allowing them to develop *in vivo* resulted in quail fetuses in which all definitive hematopoietic cells were derived from the quail embryo. The results from this experiment incontrovertibly ruled out any yolk sac contribution to definitive hematopoiesis after HH stage 9 in the chick. Strikingly, in the mouse, HSCs are detected after E10 (~three days after primitive erythroid cells are first detected), first in the aorta-gonads-mesonephros region and subsequently in the yolk sac. Furthermore, fragments of mouse embryo including aorta-gonads-mesonephros mesodermal precursors, isolated from precirculatory embryos, can fully reconstitute a genetically deficient adult host if the precursor-containing fragment is maintained in culture prior to transplantation. Together, these data suggest that the aorta-gonads-mesonephros region is the source of definitive HSCs, and not the yolk sac. Moreover, it has been suggested that some of these aorta-gonads-mesonephros-derived HSCs enter the yolk sac via the circulation, thus explaining the presence of HSCs with definitive potential found later in the yolk sacs of chick and mouse around the time that primitive hematopoiesis diminishes.

Although these and other experiments have led many to conclude that the yolk sac is not a source of definitive HSCs, these data do not completely rule out that there is a primitive contribution to definitive HSCs in the fetus. The failure to detect yolk sac HSCs in mouse embryos before E11 might be explained if HSCs are present at this time, but are not yet competent to respond or home to the adult hematopoietic microenvironment when they are transplanted into adult hosts. For example, definitive HSCs can be detected in E9 – 10 yolk sacs when the yolk sac cells are transplanted into chemically myeloablated livers of newborn hosts. Grafted yolk sac cells are capable of supporting hematopoiesis in the recipients for

nearly a year after transplant. Detection of HSCs from E8 precirculatory murine yolk sacs after a period of coculture with a stromal cell line has also been observed, lending further support to the idea that definitive HSCs are produced in the same location and during the same period of embryogenesis as are primitive progenitors. Interestingly, mouse embryonic stem cells (pluripotent embryo-derived stem cells that are believed to faithfully recapitulate primitive and definitive hematopoiesis *in vitro*) cultured under conditions that promote hematopoietic specification and differentiation, give rise to clonal colonies (i.e. colonies derived from a single cell) that contain both primitive erythrocytes and definitive hematopoietic cells. These data lend some credence to the idea that primitive and definitive hematopoietic cells share a common origin. These data also point to the need for better methods to detect HSCs in embryos. In particular, identifying groups of genes that are expressed and function specifically in HSCs would tremendously aid in HSC detection.

A second possible explanation for the failure to detect yolk sac-derived HSCs is that assays that have been used to assess the origins of HSCs, such as culturing fragments of precirculatory embryos, do not address the possibility that HSCs may be generated in the early yolk sacs of chicks and mice and then migrate interstitially into the embryo prior to the onset of circulation. Interestingly, at the same time that morphological and molecular evidence of hematopoietic development is observed in mouse embryos (E7–7.5), primordial germ cells are also formed in the yolk sac. These primordial germ cells migrate into the embryo before circulation begins, reaching the gonads (in the aorta-gonads-mesonephros region) later in development. Perhaps an early population of HSCs migrates into the embryos with the primordial germ cells. To adequately address the issue of whether the murine yolk sac contributes to functional, definitive HSCs, a reliable method for performing stage-specific *in vivo* lineage analysis of mouse yolk sac derivatives is required. Unfortunately, this will not be a trivial task given the difficulty of *in utero* transplantation, the inability to culture whole mouse embryos past E10.5 and the current lack of molecular tools to direct expression of heritable lineage markers in putative yolk sac HSCs. Until suitable technologies that allow for directly testing the fate of yolk sac hematopoietic cells are created, this issue will likely remain unresolved.

Whereas the presence of definitive HSCs during primitive hematopoiesis is still debated, it is well accepted that some definitive progenitors are generated in the primitive hematopoietic site, also in a species-specific manner. For example, isolated yolk sac cells from mouse embryos can give rise to definitive erythrocytes and other definitive hematopoietic cell types under appropriate culture conditions. The kinetics with which these committed hematopoietic progenitors emerge in the mouse yolk sac, and subsequently in the aorta-gonads-mesonephros and liver suggest that progenitors generated in the yolk sac enter circulation, seed the fetal definitive hematopoietic sites and contribute differentiated definitive blood cells during fetal development. Similarly in *Xenopus*, detailed fate mapping of the ventral blood islands revealed that it contributes not only to primitive erythrocytes, but also to a small but significant number of thymocytes (T-cells) and B-cells in premetamorphic animals. A small contribution of ventral blood island cells to definitive erythrocytes and

thymocytes is also detected postmetamorphosis, when the bulk of definitive hematopoietic cells are derived from the dorsolateral plate. Thus, cells derived from the site of primitive hematopoiesis appear to make at least a temporary contribution of definitive progenitors to the developing embryo.

In summary, primitive hematopoiesis occurs in a unique site and produces the first circulating red cells and leukocytes of the developing embryo. Although differentiated primitive blood cells play only a transient role in development, numerous lines of evidence point to a lasting contribution of definitive progenitors and, potentially, some definitive HSCs that are generated in the primitive hematopoietic site. In the following sections, we will review what is known about the molecular regulation of primitive hematopoiesis including the specification and maturation of primitive hematopoietic cells as well as tissue interactions that influence these events.

2 Specification, Expansion and Differentiation of the Primitive Erythroid Lineage

As discussed above, one of the main functions of primitive hematopoiesis is the generation of large numbers of primitive erythrocytes. In this section, we will briefly review what is known about the molecular regulation of primitive erythropoiesis, including the signals that regulate ventral patterning of the mesoderm, from which primitive blood is derived, the specification of hematopoietic fate within this mesoderm, and the subsequent production, expansion, survival, and differentiation of progenitors into primitive erythrocytes (summarized in Fig. 2). We have elected to focus on primitive erythrocyte differentiation because relatively

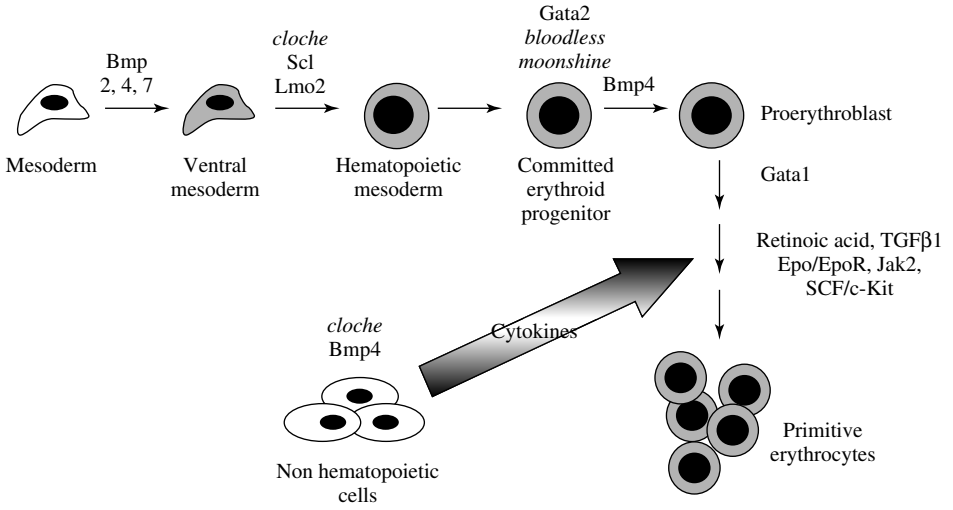

Fig. 2 Primitive erythropoiesis. Genes required for different steps of the erythroid development pathway are shown in plain text, and zebrafish mutants that block erythroid development at various steps are shown in italicized text. For details, see text in Sects. 2 and 3.

little is currently known about primitive leukocyte development.

2.1 The Signal to become Ventral

Primitive and definitive hematopoietic cells are derived from mesoderm, the germ layer of the embryo that gives rise to notochord, kidney, muscle, bone, blood, blood vessels, and heart. Early in development, mesoderm is specified and is subsequently patterned along the dorsal/ventral (D/V; back/belly) axis. The dorsalmost mesoderm is the notochord, whereas the ventralmost mesoderm is the primitive blood. D/V patterning of mesoderm is largely regulated by bone morphogenetic proteins (BMPs), secreted signaling molecules of the transforming growth factor-β (TGF-β) superfamily. Numerous BMPs have been identified in vertebrates; however, existing evidence suggests that *bmp2, 4,* and *7* are most likely to participate in D/V patterning of nascent mesoderm.

BMPs are proposed to act as morphogens in patterning the mesoderm. A morphogen is a substance that is present in a gradient and elicits a range of specific developmental outcomes (mesoderm patterning in this case) in a concentration-dependent manner. Convincing evidence in support of this theory comes from studies of *Xenopus* and zebrafish embryos in which BMP signaling is incrementally increased or decreased. Increasing the dose of BMP4 in developing embryos (by injecting increasing amounts of *bmp4* mRNA into embryos) leads to formation of mesoderm with increasing ventral character at the expense of dorsal mesoderm. Conversely, decreasing the amount of BMP4 signaling (by injecting increasing amounts of mRNA encoding a dominant-negative BMP receptor) leads to the production of increasingly dorsal mesoderm at the expense of ventral mesoderm. Thus, high levels of BMP signaling specify the most ventral fate (primitive blood), lower levels of BMP signaling specify an intermediate cell fate (pronephros, the functional equivalent of kidney, and definitive blood), and low or absent levels of BMP signaling specify the most dorsal cell fate (notochord, somites) within the mesoderm. Similarly, in zebrafish, a series of BMP signaling mutants has been generated from large-scale mutagenesis screens. Those embryos with the most severe losses of BMP signaling display the most dorsalized mesodermal phenotypes whereas those with the most active BMP signaling display the most ventralized phenotypes. In mouse, *bmp4*, but not *bmp2* or *bmp7*, appears to play a role in the specification of ventral mesoderm. In the absence of *bmp4*, ventral derivatives, including primitive blood and endothelium, fail to form in the yolk sac. Many questions remain as to how BMPs regulate mesodermal pattern. For instance, the direct transcriptional targets of the BMP signaling pathway have not been well characterized. In addition, it is not yet clear how quantitative changes in BMP signaling differentially regulate expression of these target genes. Furthermore, the timing of BMP action on D/V patterning of each mesodermal type during early development and whether BMP acts on each mesodermal type directly or indirectly (for instance, through signaling in surrounding tissues) is not well characterized.

2.2 Specifying Primitive Hematopoietic Cell Fate

After the nascent mesoderm has been patterned along the D/V axis, a subset of the ventral mesoderm is specified as

hematopoietic. Gene targeting in mouse (i.e. the creation of a mouse in which a gene is "knocked-out" or mutated) has identified genes that are required for this process. One such gene is the basic helix–loop–helix transcription factor *scl/tal1*, which is expressed in the nascent ventral mesoderm, prior to overt differentiation of hematopoietic cells in all vertebrates. Mice that are homozygous for a nonfunctional allele of *scl* fail to generate any primitive erythrocytes in otherwise normally patterned embryos. Analysis of gene expression in these mutant embryos, as well as hematopoietic culture assays using mutant tissues and cell lines, demonstrated that *scl* is required for both primitive and definitive hematopoiesis. Consistent with these data, overexpression of *scl* in zebrafish embryos leads to excessive commitment of mesoderm to a primitive hematopoietic fate. Similarly, overexpression of *scl* in dorsal mesoderm of *Xenopus* embryos leads to ectopic production of primitive erythroid cells without otherwise altering the dorsal fate of this tissue. Collectively, these data are consistent with the hypothesis that *scl* functions after the induction and ventral patterning of the mesoderm to specify primitive hematopoietic fate.

The transcription factor *lmo2*, which contains LIM protein interaction domains but no DNA binding domain, is expressed in the prospective hematopoietic mesoderm in a pattern similar to *scl*. Targeting of *lmo2* in mouse confirms a role for *lmo2* in specification of primitive and definitive hematopoietic fate. Overexpression of *lmo2* in *Xenopus* is not sufficient to induce ectopic primitive hematopoiesis, whereas, coexpression of high levels of *lmo2* and *scl* can induce ectopic primitive erythrocytes, suggesting both factors must be present for a cell to adopt a hematopoietic fate. Physical interactions between *lmo2* and *scl* have been detected in mammalian erythroid cell lines, suggesting that *scl* and *lmo2* may form transcriptional complexes that regulate genes required for primitive hematopoiesis.

The regulatory steps that occur between ventralizing the mesoderm and expression of *scl* and *lmo2* are extremely important, but little is known about them. In zebrafish, a spontaneous mutant, *cloche*, has been identified that may reveal much about hematopoietic specification during primitive hematopoiesis. In *cloche* mutants, expression of *scl* and *lmo2* is absent or severely reduced and the intermediate cell mass contains no morphological evidence of the presence of erythroid progenitors. The gene encoded by *cloche* appears to act upstream of *scl* since forced expression of *scl* in *cloche* mutants leads to partial rescue of primitive erythrocytes. Thus, identifying the gene that encodes *cloche* will be a critical step towards gaining a complete understanding of the early events of hematopoietic development, including the regulation of genes required for hematopoietic specification.

2.3 Regulating the Production, Expansion and Survival of Primitive Erythroid Progenitors

Hematopoietic mesoderm gives rise to multipotent and unipotent progenitor cells that must make decisions regarding whether they should proliferate, undergo apoptosis, or differentiate. Each of these decisions is tightly regulated by a combination of extrinsic and intrinsic signals. In the mouse, the cytokine *vegf* and its tyrosine kinase receptor *vegfr2/flk1* have been shown to be required at an early stage for the initial production of primitive erythroid progenitors. Mice mutant

for *vegfr2* lack all blood and blood vessels, possibly because of failure to recruit blood and endothelial progenitors to the correct site where they can receive signals necessary to commit to an erythroid fate. VEGF may also be required for progenitor expansion since cultures of *vegfr2*$^{-/-}$ ES cells generate reduced total numbers of hematopoietic progenitors relative to wild type cells. In zebrafish, *vegfr2* mutants produce normal numbers of primitive erythrocytes, suggesting that either VEGF signaling is not required for hematopoiesis, or that another *vegfr2* locus exists. The latter possibility is feasible as many genes are duplicated in the zebrafish genome. In the chick, VEGFR2 is expressed in prospective hematopoietic mesoderm, and it has been demonstrated that VEGFR2 signaling is required for hematopoietic colony formation in cultures of prospective yolk sac mesoderm. However, addition of VEGF to the culture media does not promote hematopoietic colony formation, suggesting that a different member of the VEGF family or a related cytokine may bind to VEGFR2 and promote hematopoiesis.

A second gene product that is required for primitive erythropoiesis is *gata2*, a member of the GATA family of zinc finger transcription factors. *gata2* is expressed in all vertebrate embryos in a pattern consistent with a role in early hematopoiesis and *gata2*$^{-/-}$ mouse embryos contain two- to sevenfold fewer circulating primitive erythrocytes. Culture of mouse *gata2*$^{-/-}$ embryonic stem cells (ES cells) and yolk sac cells in conditions that favor the expansion of hematopoietic progenitors (both primitive and definitive), revealed that lack of *gata2* caused a decrease in the total number of all progenitors, including erythroid progenitors. *gata2* expression and/or activity may be regulated by cytokine stimulation, as numerous cytokines can induce the expansion of HSCs and progenitors *in vitro* and *in vivo*. Although *gata2* is required for progenitor expansion, a subsequent reduction in *gata2* expression in committed erythroid progenitor cells is required for their differentiation.

Another member of the GATA family, *gata1*, is expressed at relatively early stages of hematopoietic development in all vertebrates, but its function is only required after erythroid progenitor cell commitment as evidenced by differentiation defects in animals that lack functional *gata1*. Numerous genes expressed in developing and mature erythrocytes such as *scl*, and embryonic *globin* genes contain GATA sites in their promoters/enhancers. Mice homozygous for null alleles of *gata1* seemingly lack all circulating primitive erythrocytes. Closer inspection of peripheral blood in these mutants revealed that nonhemoglobinized proerythroblasts are present and that they arrest in development and undergo apoptosis. Similarly, in zebrafish, a point mutation in the *gata1* gene that results in deletion of 79 C-terminal amino acids has been identified as the molecular basis of the *vlad tepes* bloodless phenotype. In these mutants, proerythroblasts do not enter circulation and hematopoietic cells in the intermediate cell mass (IM) do not express terminal erythroid genes.

In the mouse, homozygous mutation of the friend of GATA gene (*fog1*), a zinc finger transcription factor that physically interacts with *gata1*, arrests primitive erythroblast differentiation at the same stage of differentiation as loss of *gata1*. Fog1 and Gata1 protein interaction has been shown to be critical for definitive erythroid cell line differentiation and this interaction requires the presence of the N-terminal zinc finger of Gata1. Consistent with these observations, mice in which the *gata1* gene

has been replaced with a version of *gata1* that contains a single amino acid change that prevents binding to *fog1*, arrest at the same stage of development as *gata1*$^{-/-}$ embryos, suggesting that interactions between Gata1 and Fog1 are a requisite for normal primitive erythroid development. Numerous erythroid cell line studies have also shown that *scl* regulates definitive erythropoiesis through dynamic association with other transcription factors, including the formation of DNA binding complexes containing Lmo2 and Gata1. The recent creation of an adult hematopoietic-specific knockout of *scl in vivo* demonstrates an absolute requirement for *scl* in adult definitive erythroid lineage development. Persistent *scl* expression in erythroid progenitors and circulating primitive erythroblasts suggests that *scl* plays a similar role in primitive erythrocyte differentiation.

A number of zebrafish mutants that lack, or have a severely reduced number of circulating primitive erythroid cells have been identified. Among these mutants, *bloodless* and *cloche* appear to affect progenitor survival or expansion. The *bloodless* mutation acts as a noncell autonomously since wild type cells transplanted into *bloodless* mutant embryos cannot undergo primitive hematopoiesis. This raises the possibility that *bloodless* regulates or encodes a cytokine. In *bloodless* mutants, the onset of *scl* expression is detected at the appropriate time and place in the hematopoietic mesoderm; however, only a few cells continue to express *scl* in the intermediate cell mass and apoptosis is detected at later stages. These data suggest that although hematopoietic cells are specified, they cannot survive. The *cloche* mutation may also regulate progenitor expansion. Transplanted *cloche* mutant cells in wild type embryo hosts can occasionally contribute to the primitive erythroid lineage, but far less efficiently than similarly transplanted wild type cells, suggestive of a defect in erythroid progenitor proliferation. Identifying the genes encoded by *bloodless* and *cloche* will greatly enhance our understanding of how progenitors are maintained.

A second zebrafish mutant, *moonshine*, fails to undergo erythroid progenitor commitment. In *moonshine* mutants, *gata2* expression appears normal in hematopoietic mesoderm, indicating that uncommitted hematopoietic progenitors are present. However, *gata1* expression is absent suggesting that committed erythroid progenitors do not develop in the absence of the *moonshine* gene. The gene encoded by *moonshine* has not yet been reported, and its characterization will undoubtedly provide insights into how hematopoietic gene expression is regulated. Other approaches to identifying genes that are critical in primitive erythroid development have been fruitful. In the mouse, a critical role for BMP4 in erythroid progenitor commitment has been revealed through studies of primitive erythroid differentiation in cultured ES cells. Specifically, hematopoiesis can be blocked at the uncommitted progenitor stage when cells are cultured in the absence of serum. The addition of BMP4 to culture media promotes the expression of *gata1* and primitive erythrocyte differentiation, whereas blocking BMP signaling in erythroid cells by expressing a dominant-negative BMP receptor with an erythroid-specific promoter prevents *gata1* expression and erythroid differentiation. Thus, both *moonshine* and BMP signaling are required for *gata1* expression and for primitive erythrocyte maturation.

Reductions in circulating primitive erythrocytes have been observed in mouse embryos that are defective in some cytokine signaling pathways.

Historically, cytokine function in primitive hematopoiesis has largely been ignored or dismissed, most likely because only a subset of differentiating primitive erythrocytes fail to survive in known cytokine signaling mutants. Moreover, in many cases, the embryos can survive to stages where more drastic effects on definitive hematopoiesis are observed. The erythropoietin receptor (EpoR), a member of the cytokine receptor superfamily, is expressed in the early mouse yolk sac hematopoietic mesoderm, before erythroblasts are detectable, and is also expressed in developing primitive erythroid cells at later stages of development. In yolk sac cultures, addition of EPO to the culture media increases the number of primitive erythrocytes. Conversely, introduction of antisense oligonulceotides that block *epoR* expression reduce the number of differentiated primitive erythrocytes. Mice that are homozygous null for the *epoR* gene apparently initiate hematopoietic development normally, as normal numbers of erythroblasts are present in the yolk sac at E9.5 (at this stage about half of the erythroblasts have entered circulation). However, by E10.5, circulating primitive erythroid cells are reduced by ~80%. In the remaining circulating erythroid cells, differentiation appears to occur normally, suggesting that Epo signaling is specifically required for erythroblast proliferation and/or survival. A two- to threefold reduction in circulating erythrocytes has also been reported in mouse E12 embryos that do not express *c-kit*, a tyrosine kinase receptor that binds stem cell factor/kit ligand. Analysis prior to E12 has not been reported, but a decrease in circulating blood erythrocytes at this stage may indicate a deficit in primitive erythroid survival or proliferation. The Janus Kinase (Jak) family of cytoplasmic tyrosine kinases mediates signaling through cytokine superfamily receptors, including EpoR as well as tyrosine kinase receptors, including c-Kit. A significant reduction in the number of circulating primitive erythrocytes in $jak2^{-/-}$ mice has been reported. Finally, TGF-β1 appears to also play a role in the proliferation of primitive erythroid progenitors. In some $tgf\text{-}\beta 1^{-/-}$ embryos, a large reduction in circulating erythroid cells is observed after E9.5. Together, these data not only highlight the importance of cytokines in primitive erythroid cells but also suggest that some profound differences in cell signaling exist between primitive and definitive hematopoiesis. A number of zebrafish mutants that similarly arrest primitive erythroid development after erythroblasts have entered the bloodstream have been identified and characterized. In these mutants, normal numbers of erythroblasts enter circulation, but they subsequently fail to proliferate, and in some cases, they also fail to maintain hemoglobin expression and do not fully differentiate.

Retinoic acid may also play an important, concentration-dependent role in primitive erythroid cell differentiation. Although numerous retinoic acid receptors have been knocked-out in the mouse without any major effects on primitive or definitive hematopoiesis, increases or decreases in retinoic acid do affect primitive erythropoiesis in *Xenopus* and quail embryos, respectively. For example, incubating *Xenopus* embryos in retinoic acid leads to defects in primitive erythrocyte differentiation and survival without an apparent effect on hematopoietic specification. Vitamin A-deficient quail embryos maintain expression of *gata1* in yolk sac-derived erythroblasts, but form fewer primitive

erythrocytes than wild type embryos and these erythrocytes fail to hemoglobinize. At earlier stages, an increase in apoptosis is detected in hematopoietic cells. These defects can also be mimicked in whole embryo culture by Noggin (a BMP2, −4 antagonist) and primitive erythroid development can be rescued in vitamin A-deficient embryo explants by the addition of BMP4, suggesting that BMP4 is critical for erythroblast survival and differentiation.

Additional evidence for the role of BMPs in regulating primitive erythrocyte survival and differentiation has recently been revealed by altering BMP signaling in *Xenopus* embryos. When BMP signaling is blocked specifically in the ectoderm of developing embryos, by overexpression of RNA encoding a dominant-negative BMP receptor, mesodermally derived erythroid progenitors undergo programmed cell death and very few mature primitive erythrocytes are detected in otherwise normal embryos. Thus, BMP4 signaling is required in ectodermal cells in order to generate an essential survival factor for the erythroid lineage. Upregulation of BMP signaling in the ectoderm by microinjection of RNA encoding a constitutively active BMP receptor also reduces the number of circulating primitive erythrocytes; however, apoptosis does not appear to be responsible for this decrease. Remarkably, a concomitant increase in circulating macrophages is also observed. As previously discussed, the *Xenopus* ventral blood island does make a significant contribution to circulating macrophages in embryos, suggestive of the presence of either multilineage myelopoietic progenitors or macrophage progenitors in the ventral blood island. These results raise the intriguing possibilities that BMP signaling regulates lineage commitment (i.e. the choice to become erythroid or nonerythroid myeloid cells) or specifically regulates the development of the myeloid lineage. Unfortunately, cell culture assays that are routinely used to assay the potential of mammalian and avian hematopoietic progenitors *in vitro* are not technically feasible with amphibian tissues. As discussed in greater detail in the next section, BMPs appear to act indirectly on the ventral blood island, most likely via the production of secondary signals in the ectoderm.

To summarize, numerous transcription factors, cytokines, and signaling molecules have been identified that have essential functions in the development of primitive erythroid cells (Fig. 2). First, mesoderm is ventralized through the actions of BMPs. Next, mesoderm is specified to adopt a primitive hematopoietic fate by processes that are not currently understood, but may be better elucidated once the genetic basis of the *cloche* mutant phenotype is revealed. The production of erythroid progenitors requires the transcription factors *scl* and *lmo2*, whereas maintenance of progenitors requires the transcription factor *gata2*. Signaling molecules that regulate their expression are presumed to exist, but have not been identified. The decision to commit to an erythroid fate is regulated together by *gata1* and *fog1*, and later roles for these and other transcription factors in erythroid differentiation are likely. Expression of *gata1* is regulated at the transcriptional level by cytokines such as BMP4. Cytokines such as BMP4 and EPO have also been shown to play an essential role in proliferation and survival. Numerous zebrafish mutants that block erythroid progenitor commitment and that also fail to maintain normal numbers of circulating primitive erythrocytes have been isolated. Determining which genes

are mutated in these lines will yield insights into how erythroid commitment and survival is achieved, as well as how erythroid-specific gene expression is regulated.

3 Role of Cell–Cell Interactions in Primitive Hematopoiesis

Cell–cell interactions are responsible for regulating many embryonic developmental events. Secreted signaling molecules produced by both hematopoietic and non-hematopoietic cells play a critical role in primitive hematopoiesis through effects on specification, migration, survival, differentiation, and regulating primitive and definitive potential. In the embryo, morphogenetic movements result in hematopoietic cells contacting different cell types, and thus, many microenvironments that potentially influence their development. In this section, we will review tissue–cell interactions that are known to regulate primitive hematopoiesis.

3.1 Extraembryonic Endoderm

During gastrulation in the mouse and the chick, prospective hematopoietic mesoderm migrates into the extraembryonic region, where it comes into direct contact with the extraembryonic endoderm (known in the mouse as *visceral endoderm*, or VE). Studies of cultured mouse ES cells and cultured early-mid gastrula stage mouse embryos have revealed a role for the VE in normal hematopoiesis. For example, hematopoiesis is impaired in embryoid bodies (ES cells that differentiate into structures that resemble mouse gastrulae) that are rendered VE-deficient by a genetic mutation. Likewise, removal of the VE from mid-gastrula stage mouse embryos results in their subsequent failure to specify hematopoietic precursors. Indian hedgehog (Ihh), a member of the Hh family of signaling molecules, is expressed in the VE and can substitute for VE function in hematopoietic development. Although Ihh is sufficient to substitute for the VE-derived signal, it is not required since *Ihh* mutant embryos do not display defects in blood development, possibly owing to genetic redundancy. The effect of Ihh on cultured VE-deficient embryos depends on BMP4 signaling, raising the possibility that VE-derived Ihh functions to maintain early BMP signaling, thereby allowing appropriate hematopoietic specification to occur. A similar requirement for a diffusible extraembryonic endoderm signal in chick primitive erythropoiesis has also been demonstrated, yet the identity of this signal is not known. The VE may also play an additional role in directing the migration of hematopoietic precursors since these cells are the source of *vegf* mRNA. As described earlier, VEGF and related ligands are required for the migration of prospective hematopoietic cells to a site within the yolk sac that is permissive for hematopoietic development. These findings demonstrate that VE-derived signals are essential for the initiation of primitive hematopoiesis, yet their role appears to be short-lived. At the time that morphologically distinct hematopoietic cells can be detected in the mouse yolk sac, isolated yolk sac hematopoietic mesoderm (which includes hematopoietic cells as well as endothelial cells and smooth muscle cell precursors) can differentiate autonomously in culture without the need for any exogenous factors.

3.2 Ectoderm

Numerous lines of evidence point to an essential role of ectodermally derived signals in *Xenopus* primitive erythroid development. Similar to the mouse and chick, gastrulation movements in *Xenopus* embryos bring the prospective hematopoietic tissue into close contact with a different germ layer, the ectoderm. Isolated and cultured prospective ventral mesoderm (posterior ventral blood island precursors) from early gastrula stage embryos develop ''blood-like cells'' that are not hemoglobinized and do not express globin protein. However, coculture of the ventral mesoderm fragments with fragments of prospective ectoderm from stage-matched embryos leads to robust differentiation of primitive erythrocytes. Disruption of BMP signaling in the prospective dorsal or ventral ectoderm significantly reduces the number of circulating primitive erythrocytes in animals without affecting D/V patterning. Importantly, in embryos in which BMP signaling is disrupted in the prospective ectoderm, specification of hematopoietic cells, as evidenced by *scl* expression, appears to occur normally. Moreover, normal production of erythroid progenitors occurs, as evidenced by wild type levels of *gata1* at early stages of ventral blood island development. However, at subsequent developmental stages, *gata1* expression is not maintained, *globin* expression is absent or significantly reduced, and the number of circulating primitive erythrocytes is severely decreased. In other words, blocking the ability of ectodermal cells to respond to BMPs leads to defects in primitive erythroid differentiation, whereas the specification of primitive erythroid progenitors appears to occur normally. These results strongly suggest that BMP signaling in the ectoderm induces the production of a secondary signal that acts on the prospective hematopoietic tissue to support the survival of primitive erythrocytes. It has been proposed that this secondary signal is a BMP because blocking production of biologically active BMP2, 4, and 7 in the prospective ventral ectoderm also inhibits primitive erythrocyte development, and BMPs positively regulate their own expression. Thus, in theory, inhibiting BMP signaling in the prospective ectoderm could abrogate expression of endogenous BMPs that signal to the hematopoietic mesoderm. Because BMP expression is normally extinguished in the prospective dorsal ectoderm during gastrulation, and inhibiting BMP signaling in the prospective dorsal ectoderm is sufficient to block primitive erythrocyte differentiation, the secondary signal generated by the ectoderm that signals to the hematopoietic progenitors is most likely to include a cytokine or cytokines other than or in addition to BMPs.

3.3 Endothelial Cells

Endothelial cells differentiate in close physical association with primitive hematopoietic cells in all vertebrate species and some evidence suggests that endothelial cells support the differentiation of the primitive erythroid lineage. In the zebrafish, for example, transplantation of wild type cells into cloche mutants showed that in the mutant environment, wild type cells do not maintain *gata1* expression. Given that the cloche mutation also leads to the absence of endothelial cells, it has been suggested that the noncell autonomous effects on *gata1* maintenance

in erythroid progenitors is a result of loss of endothelial cells, which may normally produce factors that support *gata1* expression. Interestingly, coculture of yolk sac hematopoietic cells with an endothelial cell line significantly enhances hematopoietic cell proliferation. Thus, endothelial cells that are in close contact with developing primitive hematopoietic cells are excellent candidates for supplying critical factors that support primitive hematopoiesis.

3.4 Role of the Microenvironment in Regulating Primitive and Definitive Potential

Numerous lines of evidence suggest that the microenvironment determines the primitive or definitive potential of HSCs and progenitors. For instance, HSCs from an adult mouse can be ''reprogrammed'' to produce primitive cells by aggregating them to mouse blastocysts that are then allowed to develop normally *in utero*. In the resulting chimeric embryos, the HSCs (or cells derived from them) colonize the yolk sac and produce erythrocytes that express embryonic *globin*. In *Xenopus*, heterotopic transplantation of the dorsolateral plate (which contains definitive hematopoietic precursors) to the ventral blood island region results in dorsolateral plate-derived circulating primitive erythrocytes. Conversely, transplanting the ventral blood island to the dorsolateral plate region suppresses production of primitive erythrocytes by the ventral blood island. What regionally determines primitive versus definitive fate? Nearby tissues undoubtedly play a role through their production of extracellular signaling molecules. By using organisms such as *Xenopus* and chick that are experimentally amenable to tissue transplantation studies, it should be possible to identify the tissues that influence primitive and definitive commitment. What regulates primitive versus definitive fate intracellularly? It has recently been shown that forced expression of *hoxb4*, a homeodomain transcription factor, can reprogram primitive progenitors to produce definitive hematopoietic cells. Moreover, numerous *Hox* genes are expressed in definitive but not primitive HSCs and progenitors. Perhaps screens for secreted factors that either suppress or enhance *hoxb4* expression in hematopoietic cells may identify factors that influence primitive and definitive commitment, respectively. At the very least, determining what genes are regulated by *hoxb4* should provide some insight into how definitive potential is achieved at the expense of primitive potential.

4 Summary and Perspectives

Although primitive hematopoiesis is transient, it plays an important role in development by providing the first erythrocytes and leukocytes of the embryo. It remains to be determined if the primitive hematopoietic site contributes long-lasting HSCs with definitive potential; however, it is clear that at least in some species, some definitive hematopoietic progenitors originate there. Numerous genes, including transcription factors, secreted signaling molecules and signal transduction machinery have been shown to play a crucial role in the development of the primitive lineage through loss of function analysis in mouse, gain and loss of function studies in *Xenopus* and chick, and mutagenesis screens in zebrafish. Undoubtedly, additional genes that regulate many aspects of blood development will

be identified in zebrafish blood development mutants, now that the zebrafish genome is nearly completely sequenced. Embryological ''cut and paste'' experiments as well as perturbing signaling pathways in nonhematopoietic cells by numerous means have further revealed a complex and dynamic role for cell–cell signaling in regulating hematopoietic cell specification, potential (definitive or primitive), cell survival, and differentiation. In spite of a tremendous amount of recent progress in understanding how primitive hematopoiesis is regulated, there is still a long way to go. First, the molecular profile of primitive progenitors, and precursors at discrete stages of the differentiation process must be characterized. With the availability of techniques such as gene expression profiling, it should be possible to identify unique markers for each cell type that will allow for identifying and studying them *in situ*. Moreover, it will help identify genes that determine each cell type's characteristics. Second, a better characterization of cell–cell interactions will help identify factors that are required for various aspects of primitive hematopoiesis. Ultimately, the goal is to understand all of the signaling pathways that regulate primitive hematopoiesis. Once genes that regulate primitive hematopoiesis are identified, determining how they function within regulatory pathways will be an essential step in gaining a complete understanding of hematopoiesis.

Amino acids that are not used by living organisms.

In vitro Virus
The selection method by RNA molecules covalently bound to the protein product.

Ribosome Display
The selection method for mRNA by the function of the polypeptide displayed on ribosome stalling during the translation process.

A disrupted cell is capable of synthesizing protein from amino acids depending upon the template RNA. This discovery, half a century ago, set the stage for biochemical studies on the gene expression process occurring in cells. The cell-free translation system successfully revealed the function of a number of key molecules participating in the translation system, such as ribosome, mRNA, tRNA, and protein factors and, moreover, elucidated the very complicated mechanism of protein synthesis. Although still frequently utilized in these experimental studies, cell-free translation is beginning to make a mark as an attractive tool for protein production as a potential alternative to an *in vivo* expression system. Moreover, the cell-free translation system is prospective as a method for the synthesis of protein with unnatural amino acids and for the selection of genotypes from peptide libraries.

1 History

1.1 Beginning

Proteins are translated on ribosomes from mRNAs transcribed from DNA. The outline of how translation proceeds had been elucidated by both *in vitro* and *in vivo* approaches for two decades after the discovery of the double-helix structure of DNA. In the 1950s, most studies focusing on the gene expression process were carried out on the basis of a genetic approach using bacteria and phages. The hypothesis of the central dogma, DNA makes the RNA that makes protein, had been evidenced by various observations obtained from *in vivo* experiments. However, the precise mechanism of translation, such as deciphering information on mRNA, had to await a series of verifications by the *in vitro* translation system using disrupted cells. The first demonstration of protein synthesis using cell-extract was described by Zamecnik's group in 1952. The finding that rat liver extract was capable of incorporating amino acids into polypeptides allowed us to elucidate the involvement of individual molecular players in the gene expression process. Thereafter, it was shown in 1955 that the ribonucleoprotein complex, which was designated as ribosome, catalyzes the peptide bond formation. Up to 1960, the construction of bacterial cell-free translation systems had been achieved by several

groups. The addition of viral genomic RNA resulted in a large increase of amino acid incorporation into polypeptide, concluding that RNA serves as a template for protein.

1.2 Determination of the Genetic Code

One of the most remarkable contributions of the cell-free translation system in molecular biology was the determination of the genetic code in the 1960s. Matthaei and Nierenberg demonstrated that the addition of exogenous artificial RNA to the cell-free translation system enhanced the incorporation of particular amino acids into polypeptides. The first demonstration was that, in the presence of the polyurdylic acid (poly U), in *Escherichia coli*, the cell-free translation system was capable of synthesizing polymers of only phenylalanine at higher magnesium concentrations than physiological conditions. This finding in 1960 lead to the determination of the correspondence of the triplet codon to amino acid over the next five years. For instance, it was immediately shown that poly C was able to stimulate proline incorporation into polypeptide, indicating that the codon CCC corresponded to proline. By the various synthesized RNAs consisting of randomized two or three kinds of nucleotides, the stimulation of the incorporation of amino acid into the polypeptide was examined, and the relationship between codons and amino acids was determined using these polynucleotides. However, this approach came to a standstill because statistical speculation resulted in ambiguity.

This problem was solved by the elegant experiment called the *triplet-binding experiment*, in which aminoacyl tRNA charged with cognate amino acids binds synthesized trinucleotide on ribosome and determined the correspondence of amino acids to triplet codons. Simultaneously, the chemically synthesized oligonucleotide with a defined sequence was employed for examination of the incorporation of amino acid into polypeptides. Together with these results, the genetic code table had been established by 1966.

Another contribution of the cell-free translation system was the direct verification that tRNA is an adaptor molecule linking amino acids to codons on mRNA. The existence of an adaptor molecule had been proposed by Crick, which had not been evidenced with any experimental results. In 1957, Hoagland and Ogata independently found that the small soluble RNA molecule, which would later be named tRNA, was charged with amino acids. Nierenberg's triplet-binding experiment leads us to the conclusion that this tRNA molecule plays the role of the adaptor molecule that deciphers comma-less triplet codons on mRNA. The determination of the primary structure of tRNA by Holley demonstrated that tRNA folded in cloverleaf structure fulfills the decoding function based upon the interaction between the anticodon and codon.

1.3 Elucidation of Factors Involved in the Translation Process

To evaluate the role of protein factors involved in the translation process, the cell-free translation system has appeared to be the most useful system. The translation process proceeds in three steps: initiation, elongation, and termination, in which specific protein factors govern a respective refined process. These factors were first discovered to enhance protein synthesis using cell-free translation, and the detailed behavior was elucidated by a well-defined system capable of verifying the elementary

steps. In the case of the elongation process, Elongation Factor (EF)-Tu was first found to be a factor that stimulates poly U-dependent polyphenylalanine synthesis and thereafter it appeared to convey aminoacylated tRNA to the ribosome as a GTP-binding form. EF-Ts were shown to catalyze the exchange of GTP to GDP on EF-Tu. EF-G appeared to catalyze the hydrolysis of the triphosphate of GTP depending on the ribosome and appeared to be involved in the translocation of tRNA from the A-site to the P-site.

In the case of the initiation process, initiation factor-2 (IF-2) was shown to carry initiator tRNA attached by formymethionine onto a 30S subunit of ribosome. Initiation factor-3 (IF-3) was indicated to dissociate 70S ribosome resulting from the termination reaction. Initiation factor-1 (IF-1) was found to enhance the disassembling activity of IF3 by entering an inter-subunit space. Regarding the termination process, release factor-1(RF-1) and release factor-2 (RF-2) enter the A-site of the ribosome depending on the termination codons to catalyze the hydrolysis of peptidyl-tRNA on the P-site of ribosome. RF-1 recognizes UAG and UAA codons, while RF-2 is responsible for UGA and UAA. While the function of these two RFs was verified at an early stage of the study on translation, RF-3 and the ribosome recycling factor (RRF) had remained less understood. Very recently RF-3 was shown to be involved in the release of RF-1 and RF-2 from the ribosome. RRF was first discovered as a factor enhancing the activity of the cell-free translation system and shown to promote the dissociation of mRNA and tRNA from the ribosome.

Similarly, eukaryotic translational factors have been studied by the cell-free translation system. Although most essential factors coincide with bacterial factors, finding a number of additional proteins enhancing the cell-free translation system, especially in the initiation process, suggests that the eukaryotic system appeared to be much more complicated than the bacterial system.

2 Applications

2.1 Protein Production

Although having long served as a useful system for the elucidation of the translation mechanism, the cell-free translation system had been paid only slight attention as a tool for the preparation of protein. Most protein productions at present are based upon the expression system of cloned genes in living cells, in which we sometimes undergo failure, particularly in cases of toxic or unstable proteins. Therefore, it was desired that an *in vitro* gene expression system using the cell-free translation system would compensate for the *in vivo* expression system. However, the low yield of protein product had hindered the utilization of the cell-free translation system. The conventional cell-free translation system using crude extracts, such as *E. coli* S30, rabbit reticulocyte lysate and wheat germ extracts, produces translation reactions for no longer than 1 h in the batch system and synthesized protein products to such a small degree as to be detected only by labeling with radioactive amino acids. To improve productivity, transcription/translation, coupled with using phage RNA polymerases such as T7 or SP6 RNA polymerases, and energy regenerating systems for ATP recycling such as creatine phosphate/creatine kinase or phosphoenolpyruvate/pyurvate kinase

systems, had been developed, though both showed limited results.

However, the short lifetime of the cell-free translation system was overcome by the development of the continuous-flow cell-free (CFCF) system by A Spirin's group in 1988. In CFCF, prolongation of the reaction was achieved by the continuous feeding of amino acids and energy components, and continuous removal of reaction products. The reaction was carried out in a chamber connected to a reservoir to supply the substrates, ATP, GTP, and amino acids, by pumping, and the reactor was separated at the outlet by a membrane facilitating permeation of the synthesized protein and a low molecular weight reaction product (Fig. 1a). By this system, it appeared that the reaction using wheat germ extract proceeds for up to 100 h and was able to synthesize 120 to 240 μg of protein in a 1-mL reaction chamber. The most plausible explanation for this long sustainability is that the shortage of an energy source such as ATP and GTP during the reaction is compensated by the supplement of a feeding solution, considering that in the batch system using cell extracts, the ATPase inevitably dwelling in the extract rapidly consumes ATP. The simpler system without the aid of pumping was developed on the basis of the dialysis method of low molecular weight compounds and designated as the continuous-exchange cell-free (CECF) system (Fig. 1b).

The improvement of productivity and reproducibility of cell-free translation has also been achieved by examining the reaction condition and preparation procedures of crude cell-extract. Preparation of crude extract from polished wheat germ ensures constant production of proteins and prolongation of reaction in the CFCF system. By washing the embryo, endogenous inhibitors of translation, including ribosome inactivating proteins (RIP) such as ricin toxin, are successfully eliminated from extracts, which may result in such drastic

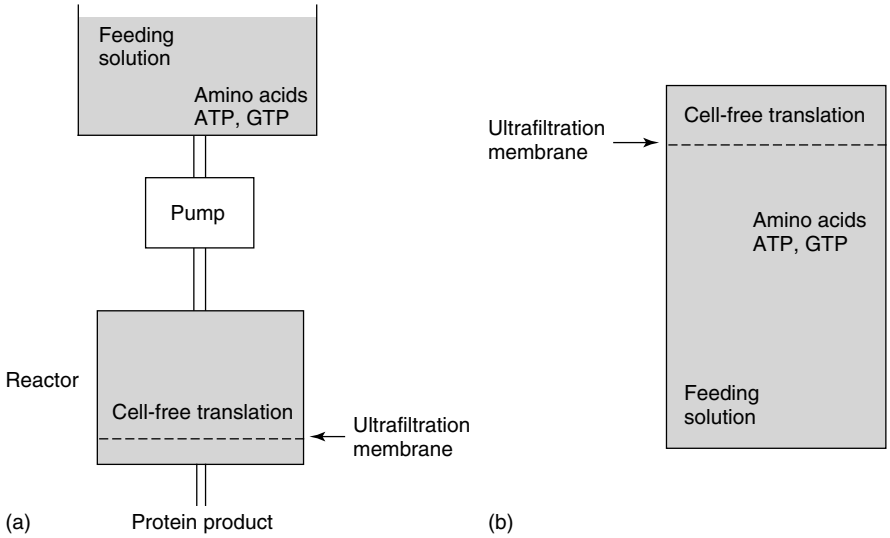

Fig. 1 Schematic illustrations of (a) CFCF and (b) CECF translation systems. A feeding solution containing ATP, GTP, and amino acids is supplied to the reaction chamber in which cell-free translation proceeds, by pumping (CFCF) or diffusion (CECF).

extensions of reaction and high yields of proteins. More recently, a reconstruction of the cell-free translation system using purified components was successfully achieved. Three initiation factors, three elongation factors, three release factors, RRFs, 20 individual aminoacyl tRNA synthetases and methionyl-tRNA transformylase were cloned from the *E. coli* genome for efficient expression in *E. coli* cells and purified. This reconstituted system, designated as the Protein synthesis using recombinant elements (PURE) system, is capable of synthesizing approximately 0.1 mg of proteins in 1-mL volume per hour without any supplemental system such as CFCF and CECF.

2.2 Synthesis of Artificial Protein

One application of cell-free translation is the incorporation of unnatural amino acids into polypeptides. The amino acid–comprising proteins are canonically confined to 20 kinds, barring exceptions such as selenocystein, and therefore *in vivo* systems are unable to synthesize proteins with other amino acids. In 1989, Shultz's group developed a method to incorporate unnatural amino acids at a desired position in polypeptides using the cell-free translation system. In this system, as illustrated in Fig. 2, synthesized suppressor tRNA are first attached by a chemical or enzymatic method to unnatural amino acids and subjected to cell-free translation for DNA templates possessing amber codons at the desired position. The attachment of unnatural amino acids is mostly carried out as follows. An unnatural amino acid is first attached to 3′ OH of adenosine of pCpA dinucleotide by a chemical method. Later, the resultant aminoacylated pCpA is ligated to an amber suppressor tRNA lacking a 3′-terminal CA sequence using

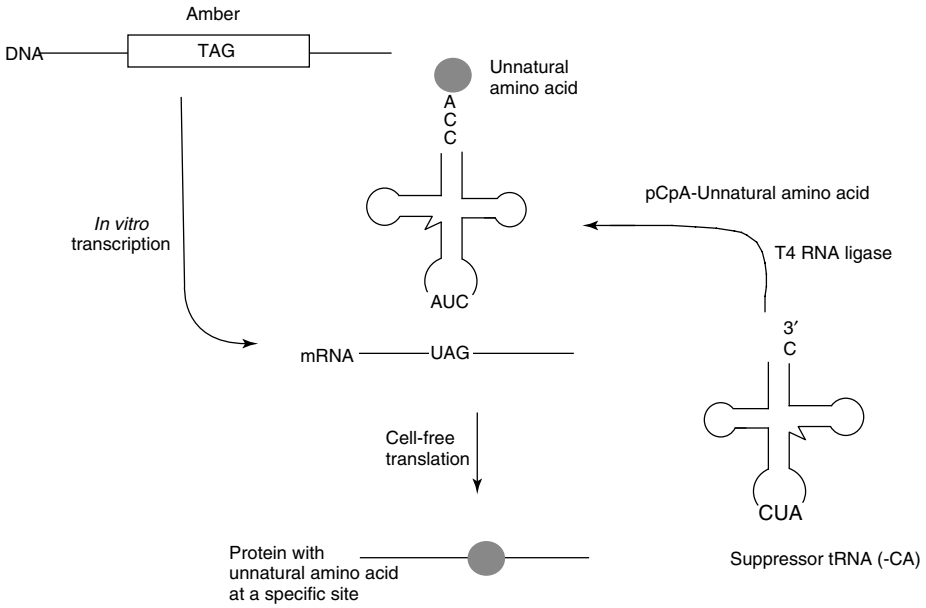

Fig. 2 Strategy for incorporation of unnatural amino acid into polypeptide using the cell-free translation system.

an RNA ligase. If unnatural amino acids are good substrates for aminoacyl tRNA synthetases, they can be attached to tRNA by an appropriate aminoacyl tRNA synthetase. The unnatural amino acid ligated to a suppressor tRNA is further subjected to the cell-free translation system and the codon-forming base pairing with the anticodon of suppressor tRNA is translated into a proteinogenic amino acid.

Although the incorporation of an unnatural amino acid into a polypeptide using cell-free translation is highly advantageous compared to an *in vivo* system, there are several problems to be solved. One problem is the aminoacylation of the suppressor tRNA after one reaction cycle of translation. The suppressor tRNA recharged by an aminoacyl tRNA synthetase during cell-free translation inserts a canonical amino acid at the amber codon, which hinders the efficient incorporation of unnatural amino acid. To solve this problem, tRNAs that are not recognized by an endogenous aminoacyl tRNA synthetase has been developed. For instance, taking advantage of the fact that yeast $tRNA^{Tyr}$ and $tRNA^{Gln}$ do not serve as a substrate for the *E. coli* cognate aminoacyl tRNA synthetase, the suppressor tRNA having the framework of yeast tRNAs is utilized as an adaptor tRNA for unnatural amino acids in an *E. coli* cell-free translation system to prevent recycling of tRNA. *E. coli* $tRNA^{Tyr}$, which is not recognized by the eukaryotic tyrosyl-tRNA synthetase, can be utilized in wheat germ extract and *vice versa*. Another problem is that the presence of RF-1 corresponding to the amber codon in the extract caused the termination to produce an incomplete peptide, reducing the percentage of peptide containing unnatural amino acid. Using the cell-free translation system in which all the components are in a purified state, this competition is circumvented by eliminating RF-1 from the system, achieving almost full suppression efficiency.

Another problem in the amber suppressor strategy is that only one codon in the open reading frame is available for the introduction of unnatural amino acids. To allow the incorporation of several varieties of unnatural amino acids into a single polypeptide, the four-base codon method was developed. In this approach, tRNA having a four-base anticodon is synthesized by transcription reaction using RNA polymerase, and chemically aminoacylated, followed by cell-free translation. By the four-base codon–anticodon method, one is enabled to incorporate multiple unnatural amino acids at plural codons. Obviously, due to competition with endogenous tRNAs, incorporation of an unnatural amino acid into the polypeptide never reaches full yield, but by employing the four-base codons competing with minor three-base codons, the efficiency of incorporation is easily improved, depending on the amount of endogenous tRNA. This artificial genetic code can be expanded by exploiting the five-base anticodon tRNA.

The expansion of the genetic code in cell-free translation was challenged by the utilization of unnatural nucleobases in codon and anticodon correspondence. The utilization of one additional artificial base pairing besides A-U and G-C pairing in the translation process is able to, in principle, extend the canonical 64 codons to 216 ($6 \times 6 \times 6$) codons in the genetic code, which gives rise to a vast possibility for the incorporation of various unnatural amino acids into polypeptides. First, isoC and isoG (Fig. 3a) were introduced in the codon and anticodon, respectively, and the resultant artificial codon corresponded to the unnatural amino acid. Recently,

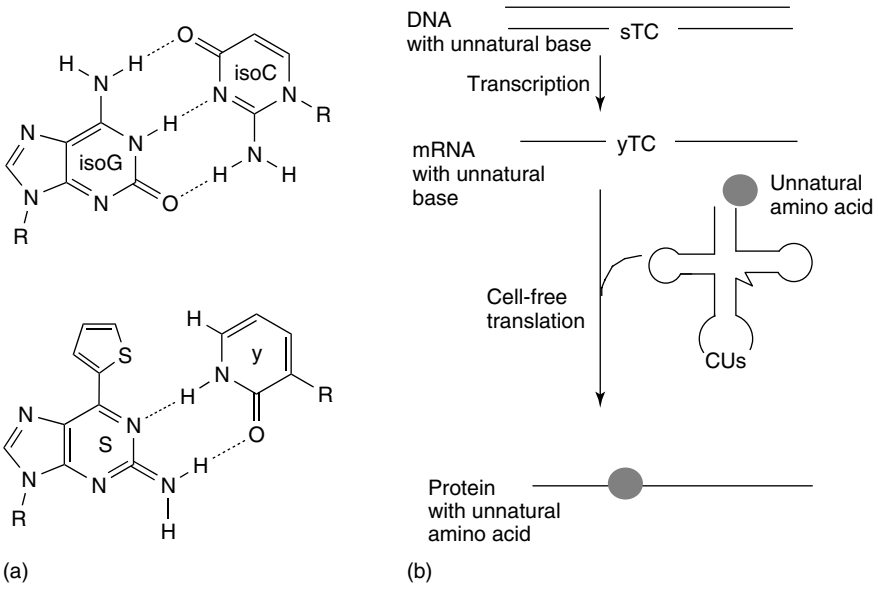

Fig. 3 Structures of unnatural bases utilized in (a) cell-free translation for expansion of genetic code and (b) design of transcription/translation coupled system using unnatural nucleotides for incorporation of unnatural amino acids.

the incorporation of 3-chlorotyrocine was successfully inserted into the desired position of protein utilizing base pairing between 2-amino-6-(2-thienyl) purine (*s*) and pyridin-2-1 (*y*) (Fig. 3b) as follows. First, a DNA fragment in which the *s*-nucleotide was located at the first letter of the desired codon was synthesized for the synthesis of mRNA by transcription reaction in the presence of the *y*-nucleotide. Simultaneously, yeast $tRNA^{Tyr}$ with the *s*-nucleotide at the third position of the anticodon was prepared by ligation of RNA fragments and was aminoacylated with 3-chlorotyrosine using tyrosyl-tRNA synthetase. Using the *E. coli* cell-free translation system, 3-chlorotyrosine was successfully incorporated at the desired position of a target protein. Although this approach looks very expansible, technical difficulties in site-specific introduction of appropriate artificial nucleobases into mRNA and tRNA remain to be solved for the development of a concise and widely distributed system.

2.3 Linkage between Genotype and Phenotype

Cell-free translation provides the potential methodology for linkage between genotype and phenotype. *In vitro* screening of DNA corresponding to RNAs and proteins with certain functions is of significant importance in the field of molecular biology. In the case of functional RNA, such as ribozymes, it is easy to convert to DNA using the reverse transcriptase after the selection procedure designed for the desired function. In contrast, we have no direct system to convert from polypeptide to mRNA. However, the complex formation of nucleic acid and its protein product enables one to perform pseudoreverse translation.

In order to link polypeptide and mRNA, two approaches using cell-free translation are now available: (1) the "*in vitro* virus" method and (2) the ribosome (or polysome)-display method.

In the "*in vitro virus*" method, creation of a covalent linkage of bonding between the mRNA and the protein is executed by cell-free translation depending on mRNA tagged with puromycin, an antibiotic with a structure resembling the 3′ end of aminoacyl tRNA (Fig. 4a). Emerging nascent polypeptide at the P-site is transferred to mRNA-linked puromycin at the A-site, giving rise to a covalent-bonded molecule of the protein product and responsible mRNA. Consequently, through the selection toward a polypeptide portion, mRNA is concurrently isolated, followed by an RT-PCR reaction of the mRNA fragment.

Meanwhile, the ribosome (or polysome)-display method is based upon a noncovalent complex formation of mRNA, ribosome, and polypeptide (Fig. 4b). The mRNA libraries are translated in the cell-free translation system and the reaction is hampered by antibiotics, for instance, chloramphenicol for the system derived from *E. coli*, or simply by cooling on ice. The stalling ribosomes display nascent polypeptides emerging from translating mRNA, and the selection is directed toward arresting the mRNA-ribosome-polypeptide complex. The isolated complex is dissociated with EDTA by splitting the ribosomal subunit, and the eluted mRNA is subjected to the RT-PCR reaction.

To ensure an efficient ribosome display, the stability of the mRNA–ribosome–polypeptide complex should be sustained

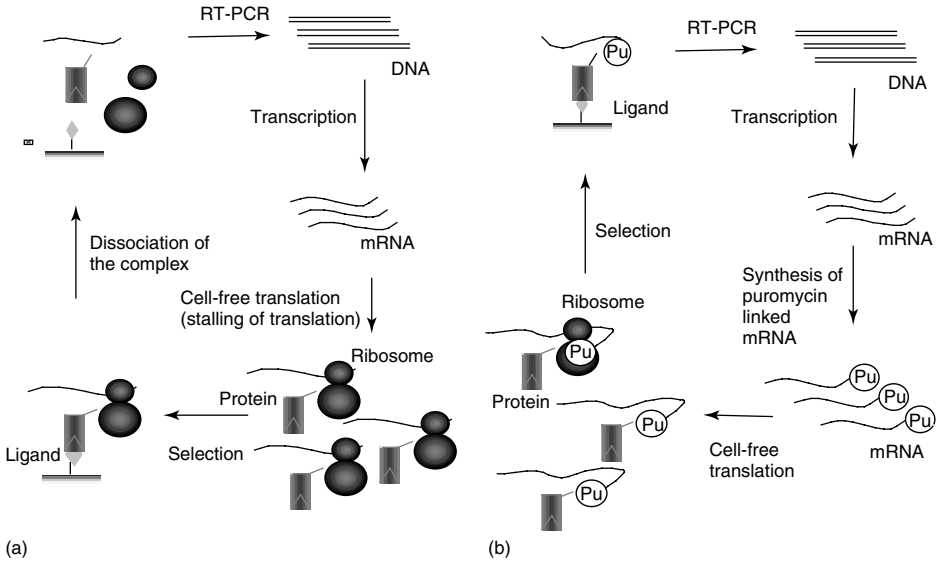

Fig. 4 Schematic drawing of two-selection method of mRNA by protein function. Ribosome display (a) is based on the selection toward attached polypeptide on stalling ribosome. The RNA-ribosome-polypeptide complex is screened by immobilized ligand and RNA derived from a selected complex was amplified by RT-PCR. *In vitro* virus (b) is synthesized puromicin-linked mRNA, which attacks nascent polypeptides attached to tRNA on the ribosome. The covalent complex of mRNA and polypeptide is selected by the ligand and subjected to RT-PCR.

against the presence of RFs in the cell-extract of the cell-free translation system. RFs in cell-free extracts hydrolyze polypeptidyl-tRNA on the P-site, responding to the occupation of the termination codon at the A-site, causing a problematical release of the complex. To prevent this instability, mRNA lacking the termination codon should be designed. The degradation of mRNA during cell-free translation sometimes reduces recovery of the objective mRNA. Thus, nuclease-free cell-free translation systems are eagerly anticipated.

Despite these problems, these two methods allow the mRNA (genotype) to be fished out depending upon the protein function (phenotype) *in vitro*, relatively more conveniently and expeditiously than an *in vivo* system. Moreover, *in vitro* systems are capable of dealing with a huge genetic library comprising 10^{13} molecules, which is an advantage over *in vivo* systems. Particularly, RNA fragments coding for polypeptides with binding properties toward certain ligands, such as antibodies, are enriched in a cloning-independent way by affinity selection from a variety of genetic pools. The multiple cycles of *in vitro* selection and amplification of functional proteins and genes, starting from a randomized pool, can be designated as an *in vitro* evolution system.

3 Perspectives

At present, most protein production processes are carried out utilizing an expression system in living cells. However, we are now able to amplify DNA molecules in a test tube by PCR technology using a DNA polymerase and to synthesize RNA by *in vitro* transcription reaction using an RNA polymerase. Considering that these cell-free systems definitely accelerated an advance in molecular biology, the development of the cell-free translation system will also greatly contribute to studies on the structures and/or functions of proteins. Because of simplicity compared to an *in vivo* expression system, the cell-free translation system is well suited for high-throughput protein production in a postgenome era. Moreover, modification of the translation process is so easily achieved that we will be able to develop an artificial system in addition to synthesis of protein with unnatural amino acids, the *in vitro* virus method and ribosome-display method.

Keywords

$[Ca^{2+}]_i$ (Concentration of Intracellular-free Calcium)
When the egg is fertilized, there is a large rise in $[Ca^{2+}]_i$ that propagates across the entire cell, and in mammalian eggs this is followed by oscillations in the level of intracellular-free calcium.

CaM KII (Calcium/Calmodulin-dependent Protein Kinase II)
In the egg, it is involved with the meiotic metaphase II to anaphase II/telophase II transition.

Cytoskeleton
A complex network of protein filaments within a cell that continuously reorganizes to adopt different shapes and functions.

Egg Activation
A process that converts an egg into a zygote. It is naturally triggered by fertilization but can be experimentally induced by calcium ionophore.

Signal Transduction
Relaying of an extracellular signal into a cell then amplifying the signal quickly within the cell to create a cellular response.

MAP Kinase (Mitogen-activated Protein Kinase)
Mediates the events triggered by extracellular signals in the egg. Prohibits pronuclear formation and appears to be responsible for the changes in the organizational state of the microtubules (interphase to metaphase).

Molecular Scaffold
Cellular structures that localize elements of assembly pathways and provide a means for different kinase pathways to interact in discrete regions of the cell.

PKC (Protein Kinase C)
General cytoplasmic signal inducing agent in cells. In the egg, it supports the interphase configuration of DNA and is involved with the second polar body formation and cortical granule exocytosis.

The developmental transition of fertilization is a major organizational and functional change, which initiates a rapid series of changes that restructures the egg into the zygote. A series of cytoplasmic signal transduction events mediate these changes after the sperm penetrates the egg, resulting in a rise in $[Ca^{2+}]_i$. The egg undergoes rapid structural changes that result in the extensive remodeling of this specialized

cell. Two pivotal signaling agents that mediate several of these rapid modifications in cell structure are protein kinase C (PKC) and calcium/calmodulin-dependent protein kinase II (CaM KII). Studies indicate that elements from several of the key signaling pathways, including PKC and CaM KII, colocalize on molecular scaffolds (i.e. meiotic spindle) in the egg and may provide a means for these pathways to interact.

1 Overview of Cytoplasmic Signaling

1.1 General

All cells, regardless of whether they are part of tissue in a multicellular organism or an individual cell functioning as an organism, are faced with the challenge of responding to the external environment. The ability to make an appropriate response to external stimuli can be critical to the functioning of a cell and, certainly, in the case of a single-cell organism, the ability of a cell to reproduce. Consequently, over evolutionary time, complex networks of signal systems have coevolved with cells that provide mechanisms, and probably backup mechanisms that permit short term, relatively rapid changes in cells in response to external stimuli. Short-term cytoplasmic signals are typically mediated through kinases, phosphatases, other enzymes, and calcium to mediate relatively rapid changes in cells. This is in contrast to long-term signaling events, which are mediated by changes in gene transcription and can require multiple days to weeks to result in a change in cell function.

There is a diverse array of short-term cytoplasmic signals, but they typically have several features in common. They have the ability to amplify and propagate the signal rapidly from the site of origin, they can be modified rapidly (e.g. phosphorylated/dephosphorylated or bound to calmodulin/calcium), and the signal(s) can be terminated rapidly. Such signals can propagate globally across the entire cell, as is the case with the calcium signals when the egg is fertilized, or they can act in discrete regions in the cell perhaps by binding to molecular scaffolds. Intracellular signals can be mediated through a variety of mechanisms such as enzyme-linked receptors, G-proteins, gap junctions, phospholipases, hormones, or calcium in a network of pathways that can be highly cross-linked. The level of free calcium in cells often has a role in mediating some portion of a signaling pathway. To keep the level of intracellular-free calcium ($[Ca^{2+}]_i$) low, cells have evolved a variety of mechanisms including enzymes and other cell proteins that are differentially regulated by the level of $[Ca^{2+}]_i$. These proteins have coevolved with mechanisms that promote low levels of intracellular-free calcium, so that an elevation of free calcium will activate or inhibit an array of calcium-dependent proteins to provide a system that can affect numerous cellular functions.

The egg, and specifically the mammalian egg, is a useful system for investigating cytoplasmic signaling events, as this unique cell must rapidly undergo a highly ordered set of changes in structure and function as a result of fusion with the sperm. If

these structural and functional changes do not occur correctly, then the organism fails to propagate its genes. Additional features that make mammalian eggs a good system for investigating signaling events include the following: (1) Inherent in the production of (as well as fertilization of) eggs are natural cell cycle arrest points. The natural cell cycle arrest points provide for synchronous release from the cell cycle arrest. This has permitted the analysis of many of the signaling mechanisms involved in the cell cycle. When eggs are employed, these pathways involve the meiotic cell cycle; only after fertilization does the first mitotic cell cycle initiate. Investigations have revealed features unique to the meiotic cell cycle, such as the function of c-mos in the cell cycle arrest. These investigations have also identified many cell cycle signaling events common to both meiosis and mitosis. (2) In mammalian eggs, the DNA is condensed in the form of chromosomes and cannot participate in transcription. Consequently, at this time in development, the regulation of changes in cell function (i.e. from egg to zygote) is under the control of cytoplasmic signaling events and occurs largely at the protein level.

The illustration (Fig. 1) indicates the pathways that have been reported to be engaged as a result of mammalian egg fertilization and cell cycle resumption. Calcium acts at the top of a hierarchy of an extensive signaling cascade and triggers more than one signaling pathway. Furthermore, in mammalian eggs, the initial calcium rise is followed by oscillations in the level of free calcium above the basal level for several hours. A recent study by Ducibella and coworkers show that calcium oscillations drive the progression of several signaling events that convert the egg to a zygote. Once the fertilization-induced rise in intracellular-free calcium occurs, other calcium-dependent pathways are activated as indicated in Fig. 1.

Calcium/calmodulin-dependent protein kinase II (CaM KII) is activated in mammalian eggs, and the activation of CaM

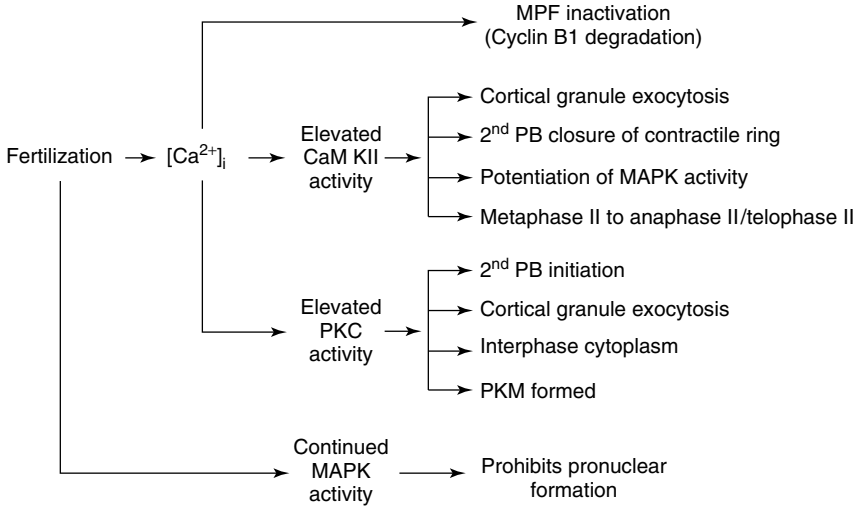

Fig. 1 The illustration indicates pathways that are involved as a result of the rise in intracellular-free calcium that accompanies mammalian fertilization. 2^{nd} PB = second polar body.

KII is dependent on the presence of both calmodulin and calcium. While functions of CaM KII have been demonstrated in eggs from other classes of organisms, there are not many reports concerning CaM KII activation in mammalian eggs. Several roles for CaM KII are summarized in Fig. 1. There is general agreement from many sources that the rise in intracellular-free calcium inactivates maturation promotion factor (MPF) by targeting cyclin B1 for degradation through an ubiquitin-dependent pathway. In addition, Protein kinase C (PKC) acts downstream of the calcium signal and there have been several reports demonstrating this activation at a biochemical or immunocytochemical level in mouse and rat eggs, although the specific isotypes of PKC that act appear to differ depending on the study and species. Once activated, PKC appears to have several roles as summarized in Fig. 1 including the release of PKC's catalytic domain (i.e. PKM). Until recently MAP kinase (mitogen-activated protein kinase) was thought to function independent of the other three pathways in Fig. 1.

1.2 Signals Regulated by Kinases

In the mammalian egg, there are three well-studied kinases that are regulated by calcium. Protein kinase C and calcium/calmodulin-dependent protein kinase II (CaM KII) are activated by calcium, while MPF is inactivated by calcium.

There are at least 12 different isotypes of PKC that range in molecular weight from about 67 to 76 kDa and all phosphorylate serine and threonine residues in protein. The isotypes are organized into three groups referred to as conventional, atypical, and novel by the cofactors required to activate the different isotypes. The conventional PKC isotypes, α, βI, βII, and γ, are activated by diacylglycerol (DAG) and negatively charged phospholipids in a calcium-dependent manner. The atypical PKC isotypes ζ and λ require negatively charged phospholipids but do not require DAG or calcium. The novel PKC isotypes δ, ε, θ, η, and μ do not require calcium but require DAG and phospholipids as cofactors. Some investigators regard PKC μ isotype as a different category of kinase because it has a unique structure. Conventional isotypes are the most likely to act proximally downstream of the calcium signal induced by fertilization of mammalian eggs because they require calcium as a cofactor. It has been shown that cells can contain more than one isotype of PKC and thus, depending on the cofactors generated, members of this kinase family have the potential to influence a variety of different pathways in a single cell as well as have different effects in different cells. The different isotypes can have different substrate specificity allowing one PKC isotype to have different effects on the cell rather than activation of another isotype in the same cell. Work with somatic cells has suggested that at least one of these isotypes, PKC λ, may serve to decode both calcium oscillations and DAG signals. These features are most likely important to mammalian eggs because not only has PKC λ been identified in mouse eggs but at least seven different isotypes of PKC have also been recently identified at the protein level in both mouse eggs and early embryos.

There are several isotypes of calcium/calmodulin-dependent protein kinase II α, β, γ, δ and, the functional enzyme is a heteromultimer composed of several catalytic subunits, but for the kinase to be active not all subunits are required. CaM KII is a large kinase with a molecular weight of 50 kDa and requires an association with calcium

bound to one or more of the calmodulin binding sites. This association activates the kinase and permits phosphorylation on serine/threonine at consensus phosphorylation sites. Once CaM KII is activated it can undergo autophosphorylation on T286/287. Consequently, it can maintain its state of activation after the calmodulin dissociates from CaM KII. CaM KII is thought to be involved with the transition from metaphase to anaphase in both somatic cells and in eggs. There is general agreement from many sources that the rise in intracellular-free calcium in amphibian eggs activates CaM KII, which then activates the ubiquitin-dependent cyclin degradation pathway and also acts on c-mos degradation. At egg activation, an increase in activity of CaM KII can be measured in mammalian eggs. By using antibodies that bind to the β- and δ-isotypes of CaM KII, it has been revealed that specific molecular scaffolds in the egg and early mouse embryo are enriched with CaM KII, as will be discussed in subsequent sections.

One well-studied calcium-dependent event involves inactivation of MPF. MPF is composed of cyclin B1 and $p34^{cdc2}$ and has been indicated as one of the kinases that drive the cell into metaphase. The rise in intracellular-free calcium that accompanies fertilization inactivates MPF by targeting cyclin B1 for degradation through an ubiquitin-dependent proteolytic pathway. MPF activity decreases in the absence of cyclin B1.

2 Coordination of Complex Signaling Pathways

There are numerous signaling pathways involved in the conversion of the egg to the zygote as outlined in an earlier section. These pathways act in a particular temporal sequence and some of the pathways appear to act on the same structure at different times progressively changing the cellular components. This is the case for the formation of the second polar body, which will be described in more detail in a subsequent section. The complexity of the changes that occur is not indicative of a system in which enzymes and specifically kinases are randomly diffused about the cells, but rather of a situation in which kinases and other components have restricted domains within the cells. Two features of the mouse egg are likely to permit the existence of these restricted domains, that is, (1) the meiotic spindle appears to be serving as a molecular scaffold that anchors elements of different signaling pathways; (2) the architecture of the egg itself is highly polarized and may restrict the distribution of signaling components including kinases.

2.1 Molecular Scaffolds

The potential for the meiotic spindle to serve as a molecular scaffold provides the opportunity to study the regulation of, and cross talk among, distinct cytoplasmic signaling pathways in mammalian eggs. MAP kinase pathways and their association with molecular scaffolds have received much study. Such scaffolds, originally identified in yeast as the Ste5 protein, have been shown to bring together many of the upstream regulatory elements in the MAP kinase pathway. Proteins with functional similarities to Ste5 have been identified in higher eukaryotes. Of particular relevance to this review, microtubules have been shown to serve as a molecular scaffold for a variety of signaling pathways including elements of MAP kinase pathways.

For example, the MAP kinases ERK1/2 have been shown to associate with microtubules. In another MAP kinase pathway, the JNK pathway, elements of that pathway (i.e. MLK2, the MAP kinase kinase kinase) associate with the microtubules through kinesin-like molecular motors.

Molecular scaffolds have been investigated in a wide variety of systems and signaling pathways. Results from these studies have led to the identification of the following putative roles for molecular scaffolds: (1) increase the efficiency of cellular reactions by optimally positioning kinases as well as their substrates and products on the scaffold; (2) decrease the response time to a stimulus; (3) enhance some forms of cross talk among pathways while reducing other forms of cross talk (by juxtaposing elements of distinct pathways on the same scaffold); (4) increase substrate specificity and; (5) localize signaling pathways to specific parts of a cell. All of these putative roles would serve useful functions in mammalian eggs since eggs must undergo a highly orchestrated regime of changes rapidly after fertilization and in the absence of new gene transcription.

There are a number of potential advantages in employing microtubules as scaffolds in mammalian eggs. First, in the mammalian egg, microtubules provide a relatively large structure that can serve as a large surface area for the binding of various proteins and components of signaling pathways. Second, the microtubules in M-phase cells exhibit a distinct polarity with their disassembly end embedded in the centrosome and the assembly end closer to the cell equator (for kinetochore and polar microtubules). Should elements of a signaling pathway be associated with a molecular motor protein or activated by something carried on a molecular motor protein, they could be positioned precisely. Third, there are three forms of spindle microtubules, namely, kinetochore, polar, and astral (in mouse eggs astral microtubules are not prominent) that may serve distinct functions for signaling pathways (for example, in the formation of midzone microtubules or in cytokinesis). Fourth, the spindle progresses through distinct, time-dependent changes after fertilization, which can serve to temporarily reposition the scaffold and associated signaling components to distinct locations in the cell at distinct times over the first 1 to 1.5 h postfertilization. Fifth, after fertilization, the meiotic spindle and its derivatives occupy a polarized location in the egg and forming zygote. All of these potential functions of the spindle microtubules as a molecular scaffold regulating cytoplasm signaling pathways could serve to orchestrate the hierarchical regime of structural and functional changes the egg undergoes in a precise spatial and temporal order as it becomes the zygote.

Studies in other systems provide evidence to demonstrate interactions between CaM KII and MAP kinase. For example, CaM KII has been shown to regulate the activity of MAP kinase in smooth muscle tissue although the mechanism of action was not determined. One study examining vascular smooth muscle cells shows that CaM KII acts upstream of ERK 1/2 through a tyrosine kinase. In neurons, CaM KII and MAP kinase colocalize on a scaffold (i.e. the postsynaptic density) and interact. The work on smooth muscle and neurons, together with our own preliminary studies, is very suggestive of an interaction between CaM KII and MAP kinase, or one of the upstream regulators, on the meiotic spindle (i.e. scaffold) in mouse eggs.

2.2 Cell Architecture

2.2.1 Action of Signaling Agents on the Cytoskeleton

The fertilization-competent egg has a variety of molecular scaffolds at distinct locations within the cell. Cortical granules that exocytose after fertilization, create a block to polyspermy and are enriched along the cell periphery of the spherical egg cell. Actin filaments also are enriched at the cell periphery, while unique arrays of intermediate filaments in the form of ''cytoskeletal sheets'' are in the cell interior and excluded from the cell periphery. The only microtubules in the cell at this time in the cell cycle are the spindle microtubules with their associated DNA in the form of chromosomes. This entire unit (i.e. the spindle and the chromosomes) at meiotic metaphase II is polarized immediately subjacent to the plasma membrane. The egg surface is covered with microvilli except for the region immediately above the meiotic spindle. Even the mitochondria have a polarized distribution with more mitochondria in the hemisphere containing the meiotic spindle.

In mammalian eggs, the microtubule network is acted on by MAP kinase to convert the interphase array of microtubules into the M-phase array of microtubules. The M-phase array of microtubules is the meiotic spindle and this appears to be serving as a molecular scaffold that is involved in the regulation of the complex signaling pathways in the egg.

The actin filament network that is greatly enriched at the cell periphery is a location where many structural changes occur. Correlative data suggest that signaling agents may act on the actin network, such as the localization of active PKC in the cell periphery, shortly after egg activation. However, there is a paucity of direct evidence for this interaction in the mammalian egg.

The intermediate filament network in mammalian eggs is composed of a highly cross-linked network of filaments in the oocyte, fertilization-competent egg, and early embryo. The intermediate filaments are composed of cytokeratins 5, 6, 16, and Z, which are produced by the maternal genome. These cytoskeletal elements referred to as ''sheets'' serve as a maternal form of intermediate filaments that are involved partly with cell adhesion events during embryonic compaction and extensively with cell adhesion as the blastocyst implants into the uterine wall. This specialized network of intermediate filaments has been identified in the fertilization-competent eggs of a variety of mammals including mouse, rat, hamster, humans, cows, and pigs. PKC acts on these ''sheets'' as part of the mechanism of downregulating the kinase. As described in more detail in an earlier section, the fertilization-induced rise in calcium activates PKC causing it to translocate to the plasma membrane. At the cell periphery, the PKC signal is downregulated by cleaving the catalytic subunit of PKC from its calcium and membrane binding domain. The catalytic subunit is then free to diffuse into the cell interior (in a form referred to as PKM) where it can phosphorylate substrates in both a membrane- and calcium-independent fashion and then PKM becomes enriched on cytoskeletal sheets. Cytokeratin 16, becomes phosphorylated, along with other components in the sheets, at the same time that this intermediate filament network undergoes extensive remodeling. A recent investigation by Coonrod and coworkers has demonstrated that a peptidylarginine

deiminase-like protein is associated with the cytoskeletal sheets and it becomes active shortly after egg activation where it may serve to aid in the reorganization of the cytoskeletal filaments in the sheets.

3 Formation of the Fertilization-competent Egg

3.1 CaM KII

Several reports have determined that CaM KII is present in the fertilization-competent mouse egg and it also is enriched on the meiotic spindle. A co-factor required for activation of CaM KII, calmodulin, is also present in the egg, but in contrast, very little of it is associated with CaM KII or the meiotic spindle in the metaphase II egg. Calmodulin, in association with CaM KII activity, which results from the basal level of $[Ca^{2+}]_i$ in the egg, has been demonstrated in fertilization-competent eggs by biochemical assays. As will be discussed later, the level of CaM KII activity greatly increases after fertilization.

3.2 PKC in the Mammalian Egg

PKC is another kinase that functions to convert the mammalian oocyte into the fertilization-competent egg. Activation of PKC has been reported to inhibit the disassembly of the germinal vesicle. Thus, one might expect that the activity of PKC would either remain constant, or be reduced, at the time of germinal vesicle disassembly. Several different PKC isotypes exist in fertilization-competent eggs of mice, although there are differences between those represented at the protein level compared to those represented at the RNA level. PKCλ and PKCμ are detected at the RNA level, while at the protein level PKCα, δ, λ, μ, and ξ are detected in the metaphase II egg. The protein level may have more isotypes because the proteins may be of maternal origin. Gangeswaran and Jones also examined mouse PKC isotypes both during the resumption of meiosis to produce the fertilization-competent egg and in the egg itself. However, they did not detect PKC isotypes α, β, γ, ε, η, θ, and ζ but detected PKC isotypes δ and λ in germinal vesicle stage oocytes at both the protein and mRNA level in metaphase II eggs. Raz et al. detected protein and mRNA for PKCα, β, γ, ε, μ, λ, and ζ in oocytes and metaphase II eggs from rat. Only conventional isotypes of PKC (i.e. PKCα, β, and γ) would be candidates for signaling agents that acted proximate to the fertilization-induced $[Ca^{2+}]_i$ since only the conventional isotypes of PKC require calcium as a cofactor for activation. Other PKC isotypes may be active at the time of fertilization, but the function of these isotypes may not be dependent on the generation of a calcium signal.

3.3 MAPK and MPF

Two important kinases that function to convert the oocyte into the fertilization-competent egg are MPF and MAP kinase. At about the time that the oocyte nucleus (i.e. the germinal vesicle) begins to disassemble, the activity of both kinases appears. There is evidence to suggest that in mammalian development, MAP kinase activity appears first, followed by MPF activity, or there is simultaneous activation of MAP kinase and MPF. Data from other investigators have indicated a reverse sequence. As Cyclin B1 is synthesized and

associated with $p34^{cdc2}$ to make active MPF, oocytes arrested in prophase I of meiosis are recruited to resume meiosis. Cyclin degradation is initiated as the oocyte transits between meiosis I and meiosis II. New synthesis of cyclin replenishes the diminished concentration of cyclin and maintains the activity of MPF. This balance of continued degradation and new synthesis of cyclin accompanies the formation of the fertilization-competent egg and explains why, when protein synthesis inhibitors are applied to eggs, the eggs subsequently activate. This is because cyclin continues to be degraded as normal but the inhibitor blocks any new cyclin synthesis. Subsequently, the arrest at meiotic metaphase II cannot be maintained because of the level of MPF. The integrity of a molecular scaffold of the cell, the meiotic spindle, plays an important role in the degradation of MPF within the fertilization-competent egg at meiotic metaphase II. Cyclin degradation is inhibited and the egg remains arrested in meiotic metaphase II if the meiotic spindle is disrupted with a microtubule-disassembling agent. In contrast, the degradation of MPF is much slower between meiosis I and meiosis II and it does not appear to be linked to the integrity of the spindle microtubules. This suggests that in a metaphase II egg, the presence of a molecular scaffold (i.e. the meiotic spindle) is associated with components that provide a mechanism to increase the efficiency of a variety of reactions including cyclin degradation. The colocalization of components on molecular scaffolds in the cell will be discussed below.

Several different MAP kinase pathways have been identified in various cell types functioning through different MAP kinases, for example, ERK 1/2, JNK/SAPK, p38, and ERK 5. The ERK 1/2 pathway has been identified in oocytes and eggs. In this pathway, the upstream activator of MAP kinase is MEK 1/2 (i.e. MAP kinase kinase). Further upstream in this kinase cascade in eggs is c-mos (MAP kinase kinase kinase), whereas in other cell types it is typically one of the Raf isotypes. When oocytes are triggered to resume meiosis from the arrest at prophase I, MAP kinase is activated. MAP kinase is dependent on protein synthesis to be initially activated because if puromycin, an inhibitor of protein synthesis, is applied MAP kinase does not become active in mouse or rat oocytes. However, once MAP kinase is activated, protein synthesis is no longer necessary to maintain MAP kinase activation. C-mos is present in mammalian eggs and is considered a part of cytostatic factor (a factor in the cytoplasm that maintains the arrest at meiotic metaphase II). It is important to note that c-mos is thought to be an upstream activator of MAP kinase and in the absence of c-mos activity, MAP kinase does not become active. Evidence of this activation pathway also comes from studies where the c-mos gene has been disrupted. In such mice, MAP kinase does not become active. Raf, which is a known upstream activator of MAP kinase, is also present in these eggs, but Raf activity was not detected when MAP kinase became active. The activation of MAP kinase requires phosphorylation on both tyrosine and threonine residues to become an active serine/threonine kinase and the application of phosphatase inhibitors speeds MAP kinase activation.

The major changes in organizational state of the microtubules (i.e. the switch from the interphase to the M-phase configuration of microtubules) as well as the disassembly of the germinal vesicle that is required for the formation of the metaphase II egg appear to be due to MAP kinase activation in the oocyte.

Inoue et al. accelerated germinal vesicle disassembly by microinjection of active MAP kinase into the germinal vesicle, which suggests that MAP kinase acts directly on components in the nucleus to mediate nuclear disassembly.

The active form of MAP kinase is enriched on the entire meiotic spindle in the fertilization-competent egg arrested at meiotic metaphase II. To demonstrate the presence of the active form of the kinase, an immunocytochemical assay was performed using antibodies that bind sites on MAP kinase that are phosphorylated only when the kinase is active. By using an antibody that recognized both forms of the kinase (i.e. total MAP kinase and active MAP kinase), the distribution of both the active and total forms of the kinase was compared. Other investigators have also reported association of total MAP kinase with the mammalian meiotic spindle; however, only the poles of the meiotic spindle were reported by the investigators to bind MAP kinase. This may have been observed because the spindles were physically isolated from the metaphase II egg before CaM KII was measured by immunolocalization, and this may have resulted in restriction of MAP kinase to the poles.

4
Activation of the Egg

4.1
Remodeling through Changes in Activity of Calcium/Calmodulin-dependent Protein Kinase II

As previously mentioned, CaM KII's activity increases after fertilization in mouse eggs; however, until recently little was known concerning the function of this activity in mammalian eggs. Johnson et al. demonstrated that CaM KII is enriched throughout the meiotic spindle in the fertilization-competent mouse egg. When either the egg or activated egg is detergent extracted to remove soluble and freely diffusing components from the cell, CaM KII remains behind and appears to be tightly associated with the meiotic spindle microtubules. In contrast, a concentration of calmodulin cannot be detected in association with the spindle in the metaphase II egg after detergent extraction, except for a window of time that is approximately 5 min after egg activation. After activation of an egg with calcium ionophore, calmodulin transiently associates with the detergent-resistant spindle 5 min after the ionophore treatment, but is absent by 15 min posttreatment. Calmodulin would bind to the increase in $[Ca^{2+}]_i$ in the egg caused by a calcium ionophore treatment. Subsequently, one would anticipate that this calcium/calmodulin complex would activate CaM KII by associating with the kinase. This reaction could be representative of the 5 min after ionophore treatment when the transient calmodulin is binding to CaM KII, which is attached to the detergent-resistant spindle. This proposal is supported by Johnson et al., who demonstrated that the level of CaM KII activity almost doubles within 5 min after egg activation, the same window of time that calmodulin is tightly associated with the meiotic spindle. In support of this finding, it was demonstrated by a recent investigation that CaM KII was active during this time interval and that a large portion of the CaM KII that is activated is enriched on the meiotic spindle.

The results described above suggest that activation of CaM KII is specifically involved with some function of the meiotic spindle. The transition of chromosomes

out of metaphase II arrest into anaphase II and subsequently into telophase II is promoted by CaM KII. This was demonstrated in two ways: (1) Living eggs were activated with calcium ionophore after the application of membrane-permeant CaM KII inhibitors, which blocked the transition from metaphase II into anaphase II; (2) When permeabilized eggs were equilibrated in a medium whose free calcium concentration was adjusted to 1 μM (using a calcium/BAPTA buffer), calmodulin was present at a concentration sufficient to establish a 4 : 1 ratio of calcium : calmodulin, and an ATP regenerating system was present; the permeabilized eggs transited through anaphase into telophase with the same timing that would occur in a fertilized living egg. As the ratio of calcium to calmodulin was sequentially dropped to 0 : 1 in the permeabilized egg, the transit to telophase was progressively reduced to zero. When inhibitors to CaM KII were applied, the transit to telophase was blocked, but other kinase inhibitors, including inhibitors to PKC, could not prevent the transit through anaphase into telophase.

The above results strongly indicate that the movement of chromosomes from meiotic metaphase II arrest into anaphase II and subsequently telophase II is regulated by activation of CaM KII. These results also explain investigations discussed earlier, which reported that when PKC is activated in mammalian eggs in the absence of an elevation in the level of intracellular-free calcium, an abnormal transit out of metaphase II occurs. CaM KII is not activated in the absence of a rise in the level of $[Ca^{2+}]_i$ and the chromosomes do not transit into anaphase, but other features of egg activation occur.

It is important to remember that Johnson et al. reported that CaM KII remains on elements of the mammalian meiotic spindle as the cell transits into anaphase and at subsequent stages. Interpolar microtubules form an overlapping assembly in the midzone region during the latter part of M-phase and the microtubules become bundled. Such midzone microtubules contain many spindle-related proteins. It has been proposed that these proteins have a role in the formation of the contractile ring during cleavage. Johnson et al. reported, in accordance with this proposal, that CaM KII appears to transit along the midzone microtubules to the contractile ring of the second polar body and localizes on the contractile ring suggesting it may play an active role in the cytokinetic process. In addition, a recent study by Hatch and Capco demonstrated that the active form of CaM KII associated with the cytokinetic ring, a structure that forms perpendicular to the midzone microtubules. This study confirms and extends on work by earlier investigators who blocked CaM KII activity with drugs. An inhibitor to calmodulin function was employed by Xu et al. and showed that this delayed the formation of the second polar body. Since calmodulin is required to activate CaM KII, the authors speculated that CaM KII activity was needed for the formation of the second polar body. This idea was further supported by two separate studies, which reported that second polar body formation was delayed after inhibitors to CaM KII were employed.

The above observations also address another paradox that was reported when PKC-induced egg activation was investigated. Gallicano et al. reported that after treatment with PKC agonists, the second polar body initially appeared, but then would frequently be absorbed into the egg. When PKC agonists are applied, there is no increase in the level of $[Ca^{2+}]_i$ and

the chromosomes do not transit normally from metaphase into anaphase. Midzone microtubules will not form since the chromosomes do not transit properly into anaphase, which could lead to an incorrect positioning of CaM KII. CaM KII would not be activated even if the kinase did translocate correctly to the contractile ring of the forming second polar body because the $[Ca^{2+}]_i$ levels would not have been elevated. Contractile ring closure may be inhibited in the absence of CaM KII activation. Without a complete separation from the egg, the second polar body may instead become absorbed into the activated egg after a period of time.

As noted in a previous section, CaM KII is tightly associated with the meiotic spindle. However, other cytoplasmic signaling agents including cyclin, c-mos, and MAP kinase have been reported to be associated with at least parts of the spindle in a variety of different systems. The presence of, or localization to, a particular site within a cell does not indicate that a kinase is in its active form. In fact, location of the greatest concentration of a kinase may differ from the site where the active kinase is positioned, as was shown in the study by Hatch and Capco that examined the distribution of CaM KII and MAP kinase in mouse eggs. This study makes use of antibodies that only recognize the active form of the kinase and other antibodies that recognize both the active and inactive forms of the kinase (i.e. the total kinase). The spatial distribution of total CaM KII and total MAP kinase was compared and indicated that the kinases colocalized on the meiotic spindle in the metaphase II egg and on the midzone microtubules after egg activation. However, very little active MAP kinase was present on the midzone microtubules and was only localized on the spindle for 25 min after egg activation. At later postactivation stages, total MAP kinase was still enriched at the midzone microtubules, but at that same location active MAP kinase was not present. In comparison, CaM KII was constantly associated with the spindle microtubules and later the midzone microtubules, whereas active CaM KII was enriched on the spindle only at 5 and 25 min after egg activation, and then enriched on the contractile ring of the second polar body 55 min after egg activation.

Colocalization of CaM KII and MAP kinase on the meiotic spindle provides the opportunity for interaction between the two kinases. This may be particularly important for CaM KII since it becomes active on the spindle 5 min after egg activation at the same time that MAP kinase also is active and associated with the meiotic spindle. An investigation demonstrated that inhibition of CaM KII activity caused a decrease in both the amount of total MAP kinase and active MAP kinase on the spindle. This study suggested that activation of CaM KII (within 5 min of egg activation) serves to potentiate MAP kinase in the active state. There are two forms of MAP kinase in mouse eggs ERK1 and ERK2. Both forms contain consensus phosphorylation sites for CaM KII. These are not the same sites that activate MAP kinase, but phosphorylation by CaM KII on these sites may prevent degradation of MAP kinases. As will be discussed in a later section, it has been proposed that the activity of MAP kinase inhibits pronuclei from forming precociously in the zygote, and after MAP kinase activity drops, pronuclei immediately form. Thus, as the means of regulating the timing of the formation of pronuclei, egg activation induces the activation of CaM KII. This CaM KII activity serves to boost MAP kinase activity

preventing pronuclei from forming too early in the zygote.

CaM KII could have two potential roles in regulating the conversion of the egg into the zygote based on the above studies: (1) to mediate the chromosomal transition from metaphase II arrest into anaphase II and subsequently through telophase II in the fertilization-competent egg and (2) to interact with MAP kinase to potentiate its activity and prevent formation of pronuclei. CaM KII is localized at an optimal site to be involved with both the above-stated roles because it is colocalized with MAP kinase. It subsequently interacts with, and it is localized on, the meiotic spindle, which is a mechanical scaffold in eggs that drives chromosomal movement.

4.2 Remodeling through Changes in Activity of Protein Kinase C

When eggs are treated with PKC agonists, fertilization-competent hamster eggs release from arrest at meiotic metaphase II, initiate second polar body formation, and several hours later pronuclei as well as the Golgi apparatus form (all components that are absent in M-phase cells). A number of the events associated with egg activation are initiated after PKC is activated in eggs using a phorbol ester (i.e. a pharmacologic agent known to activate PKC) or a diacylglycerol, a natural activator of PKC in cells. Even after inducing activation of PKC with agonists while the level of $[Ca^{2+}]_i$ was clamped low with a calcium chelator, these activation events still occurred. However, in this case the meiotic spindle did not undergo a normal metaphase to anaphase transition when the level of $[Ca^{2+}]_i$ was clamped low. Instead, the entire meiotic spindle attempted to translocate into the forming second polar body. When the reverse situation was tested (the level of $[Ca^{2+}]_i$ was elevated by experimental manipulation, and the activity of PKC was clamped low using antagonists) the eggs did not change and remained arrested at meiotic metaphase II. This indicates that PKC acts downstream of the calcium signal, although the specific isotypes of PKC that act appear to differ depending on the study and species. Even though PKC induced a number of changes that are associated with egg activation, some other calcium-dependent feature was needed to cause the normal metaphase to anaphase transition. To confirm that the fertilization-induced event involved PKC at an immunocytochemical level, the investigators monitored the spatial position of several isotypes of PKC by using a PKC reporter dye. In this study, the investigators demonstrated in hamster metaphase II eggs that as a result of the rise in intracellular-free calcium, PKCs translocated from a relatively uniform distribution in the cytoplasm to the cell periphery near the plasma membrane of the egg. Translocation of the reporter dye to the membrane indicated that the kinase was activated. In this study, a DAG, a natural simulator of PKC activity produced *in vivo*, was employed. A DAG was used because the cell itself makes DAGs and contains enzymes that normally metabolize DAG into other compounds. Thus, any DAG when transiently applied is more likely to mimic the normal activation of PKC. Phorbol esters also activate PKC but, in contrast, they are foreign to cells and could likely not be metabolized because they are not normally present in cells. Use of phorbol esters as PKC agonists could lead to abnormal results due to an extended activation of PKC as well as other

perturbations even if the phorbol ester was applied for a brief period.

Mouse eggs also have been used to demonstrate the involvement of PKC in activation. In the study by Gallicano et al., the role of PKC appeared to be identical to that described above for hamster eggs but in addition to application of DAG, sperm inseminated eggs were utilized. It was shown that sperm have the same effect as other PKC agonists, that is, after sperm penetration PKC in the egg translocates to the cell periphery. In the Gallicano et al. study, the investigators used another method, a biochemical assay, to confirm that PKC was translocating to the cell periphery at the same time that the activity of the kinase increased. In addition, at the site of second polar body initiation, PKC was shown to be enriched. Raz et al. used rat eggs to demonstrate that specific PKC isotypes translocate to the cell periphery in mammalian eggs. Upon activation of the kinase in the rat egg, PKC isotypes α, β, and γ translocate to the plasma membrane. These results fit well with the model that proposes that PKC acts downstream of the fertilization-induced elevation in $[Ca^{2+}]_i$ since, noted previously PKC α, β, and γ are calcium-dependent isotypes. This observation supports the earlier work of Gallicano et al. who, using a PKC reporter dye that detects several PKC isotypes, showed, as a result of egg activation and fertilization that PKC became active and translocated to the plasma membrane of mammalian eggs. In addition, a more recent study also supports this model. Luria et al. have examined PKC α, $\beta 1$, and $\beta 2$ in mouse eggs and report that PKCα translocates to the plasma membrane as a result of egg activation and fertilization. Two other laboratories did not detect either PKC$\beta 1$ or PKC$\beta 2$ isotypes at the protein or RNA levels in mouse eggs.

Activated PKC drives the egg into an interphase state of the cell cycle and has been shown to be involved with cortical granule exocytosis in fertilization-competent rat eggs. In the study by Raz et al., PKC was activated by both phorbol esters and DAGs and showed that activation of PKC induced both of these events. Cortical granule exocytosis in mouse eggs has also been reported after PKC is activated. However, since PKC inhibitors cannot block the fertilization-induced exocytosis of cortical granules, this indicates that the PKC pathway and other calcium-dependent signaling pathways also induce cortical granule exocytosis (Ducibella and LeFevre, 1997; Raz et al., 1998c). There is a report that inhibition of CaM KII blocks cortical granule exocytosis, but another study claims that CaM KII has no effect on cortical granule exocytosis. In mammals, the cortical granule exocytosis pathway becomes linked to calcium as the oocyte proceeds through meiosis to become the fertilization-competent egg. As mentioned above, PKC is known to translocate to the cell periphery near the plasma membrane and since the cortical granules are located in this region, PKC may serve as one of the regulators of cortical granule exocytosis. Gallicano et al. have proposed that PKC regulates the remodeling of the egg into the zygote in a very precise temporal and spatial fashion. In that model, active PKC translocates to the plasma membrane, which is induced by the fertilization-induced rise in $[Ca^{2+}]_i$. Once PKC becomes active, it is tethered to the cytoplasmic face of the plasma membrane and can phosphorylate substrates in that vicinity. It may serve to trigger a number of events including cortical granule exocytosis. One of the mechanisms

for active PKC to be downregulated is to cleave its membrane and calcium binding domains from the catalytic subunit. Once cleaved, the catalytic subunit can diffuse away from the plasma membrane while the catalytic subunit remains as an active kinase that is no longer calcium- or membrane-dependent. In this state, it has historically been referred to as PKM. Now that PKM is not membrane tethered, it can phosphorylate elements in the interior of the mammalian egg. In support of this model, Gallicano et al. have demonstrated that after activation of PKC, PKM is generated, and that it phosphorylates components of the cytoskeletal sheets and other substrates in the interior of the egg. PKC has both temporal and spatial precision because PKM can only form after PKC is activated. Thus, as a result of the fertilization-induced elevation in the level of $[Ca^{2+}]_i$, PKC initially modifies the cell periphery and then components in the cell interior are later modified by PKM. Such a model fits well with the restructuring of an egg into a zygote because, by modifying the cell periphery (i.e. cortical granule exocytosis) immediately, polyspermy is prevented and then a more gradual modification of the interior can follow.

By using pharmacologic agents that activate PKC, Moses and Kline have investigated roles for PKC in mouse eggs and have found that when such agents are applied, metaphase II eggs are driven into interphase, a characteristic of egg activation. However, transition into interphase had a different mechanism than an egg was artificially activated by calcium ionophore or inseminated by sperm. Moses and Kline report that the PKC agonist, PMA, caused abnormal and greatly slowed metaphase to anaphase transition. In part, this parallels Gallicano and coworker's results that show that eggs exhibit an abnormal transit to anaphase when PKC is activated by agonists and the level of calcium is clamped low. In agreement with this result, Moses and Kline also show that application of PMA to eggs at meiotic metaphase II does not result in an elevation in the level of $[Ca^{2+}]_i$. These results suggest that the metaphase to anaphase transition requires a component of the cell other than PKC that requires an elevation of the level of $[Ca^{2+}]_i$.

Whether activation of PKC with agonists induces second polar body formation was also addressed by Moses and Kline. The investigators conclude that even though the cell is ultimately driven into interphase, second polar body formation is not induced by activation of PKC. However, two important considerations concerning polar body formation were not taken into account. First, unlike cytokinesis, polar body formation is a two-step process in mammals, with an initial extrusion of cytoplasm (bounded by the plasma membrane) followed by formation of a contractile ring at the base of the extruded cytoplasm. Second, when PMA is applied to mouse eggs, the second polar body initially appears (initial extrusion stage), but frequently, because the contractile ring does not close, the polar body is absorbed into the egg. By the time the cell reaches telophase, the extruded second polar body appears. The cytoplasmic extrusion of the initiated second polar body can be clearly seen in figure 2b of the 1995 publication by Moses and Kline, which shows a telophase stage mouse egg. This inability of the egg to completely close the contractile ring of the second polar body suggests that some other pathway not activated by PMA is responsible for contractile ring closure. As was discussed in the previous section,

it has been suggested that CaM KII is needed for closure of the contractile ring of the second polar body.

By activating PKC with diacylglycerol, Colonna et al. conducted a detailed study to determine the role of PKC on egg activation. Their results indicate that MPF was downregulated by PKC. Colonna et al. demonstrated that the MPF level (monitored as histone H1 kinase activity) drops within 20 min of PKC activation, the chromosomes have a normal transit from metaphase to anaphase in a high percentage of eggs, pronuclei form several hours later, and the second polar body forms. These investigators used a concentration of DAG that did not increase the level of $[Ca^{2+}]_i$, but they did show that the level of $[Ca^{2+}]_i$ increases to about 0.5 μM at higher concentrations of DAG (i.e. 150 μM). This transient increase in the level of $[Ca^{2+}]_i$ may have been caused by the higher concentration of DAG because, as the DAG at this concentration intercalated into the plasma membrane of the egg, it could have affected the lipid packing in the membrane allowing calcium to leak in from the extracellular medium. The results from Moore et al., which differ from Colonna et al., did not detect either a formation of second polar bodies or a decrease in MPF activity (monitored as histone H1 kinase activity). However, to assess the effects on MPF activity, Colonna et al. employed DAGs, the natural activator of PKC in cells, and Moore et al. used phorbol esters to activate eggs. As noted previously in this section, phorbol esters, which are foreign to cells, are not as likely to be properly metabolized and regulated by cells compared to the natural activator of PKC (i.e. diacylglycerols). The unusual results may have been induced by the phorbol esters used by Moore et al.

4.3 Remodeling through Changes in Activity of MPF and MAP Kinase Activity in Activated Eggs

As discussed in an earlier section, cyclin B1 is targeted for degradation through the ubiquitin-dependent pathway by the rise of $[Ca^{2+}]_i$ in mammalian eggs, which results in the rapid inactivation (i.e. within 30 min to 1 h) of MPF, while MAP kinase activity remains elevated for a few hours and then decreases. In eggs pretreated with drugs that stabilize MPF (nocodazole and cyclohexamide), MAP kinase activity still decreased after several hours, which suggests that MPF degradation is not a requirement for the eventual degradation of MAP kinase. Just before formation of two pronuclei – one containing the male chromatin and one containing the female chromatin – MAP kinase is inactivated. The activation of MAP kinase and disassembly of the oocyte nucleus parallels the relationship between inactivation of MAP kinase followed by assembly of the nuclear envelope, that is, the nuclear envelope disassembles when MAP kinase is active. There are three lines of evidence that suggest that MAP kinase activity is incompatible with the existence of a nucleus. (1) Formation of pronuclei is inhibited when a constitutively active form of the upstream activator of MAP kinase (i.e. MAP kinase kinase referred to as MEK) were microinjected into activated eggs. (2) Formation of pronuclei is inhibited when a phosphatase inhibitor (i.e. okadaic acid) is employed to prevent dephosphorylation of MAP kinase, a treatment that maintains MAP kinase activity. (3) The oocyte nucleus disassembles when MAP kinase becomes active in oocytes, and disassembly of the nucleus occurs rapidly when activated

MAP kinase is injected into the oocyte nucleus. Thus, MAP kinase may serve to regulate both the organization of microtubules and the state of the nucleus; when microtubules are in an M-phase configuration and nuclei are absent, MAP kinase is active, whereas nuclei form and an interphase array of microtubules assemble when MAP kinase activity is reduced or absent.

One of the hallmarks of egg activation and functions to prevent polyspermy is cortical granule exocytosis, which is not under the control of MAP kinase or MPF. This was demonstrated by inhibiting protein synthesis in eggs arrested at meiotic metaphase II. It has been shown that a decrease in MPF activity is caused by a decrease in cyclin B1 concentration, which can be decreased by inhibiting protein synthesis that can also slowly decrease MAP kinase activity. Consequently, the egg will be released from arrest at meiotic metaphase II after inhibition of protein synthesis. However, cortical granule exocytosis did not occur after a decrease in MFP and MAP kinase activity, suggesting that the regulation of cortical granule exocytosis is not under the control of MFP or MAP kinase. Since a rise in $[Ca^{2+}]_i$ that accompanies fertilization or egg activation triggers cortical granule exocytosis, this suggests that a calcium-dependent component of the cell other than MPF regulates this event. In support of this assertion, the activation of another kinase, PKC (whose conventional isotypes are calcium dependent) induces cortical granule exocytosis as discussed in Sect. 4.2.

Although c-mos is reported to be an important component of cytostatic factor, an activity present in metaphase II eggs thought to arrest the egg cell cycle at meiotic metaphase II, the activity of c-mos remains elevated well after the time that MPF is degraded and the cell has proceeded into telophase. However, when using double-stranded RNA interference (RNAi) to destroy c-mos in eggs, the eggs activate indicating c-mos clearly has a role in egg activation.

5 Concluding Remarks

Signaling pathways trigger specific changes in the conversion of the egg into the zygote. This review highlighted several signaling pathways that have the potential to interact on molecular scaffolds within the egg. The egg may use these scaffolds to localize components of the various signal pathways and to allow cross talk between different pathways. Scaffolds also provide a means to promote rapid changes in the functioning and modulation of the signaling pathways. In the egg, the meiotic spindle was described as a major molecular scaffold for localizing elements of the signaling pathways to coordinate early developmental events downstream of the calcium signal.

The signaling agents that trigger many of the early events after fertilization have been identified, although clearly more work is needed to define other pathways. Much less is known of the signaling components that trigger events occurring several hours after fertilization and affecting such processes as pronuclear transcription or embryonic genome activation. These will likely be the focus of many research efforts in the future. Investigating the putative interactions between the signaling pathways can lead to improvements in cloning technology applied to agricultural animals. By studying these signaling factors, the success rates of nuclear transfer can be improved, which would make this biotechnology approach more robust.

Keywords

Chaperonin
One of a member of the family of molecular chaperones that are homologous to the *E. coli* GroEL chaperone, and the mitochondrial and chloroplast Hsp60 chaperones.

Cochaperone
A protein that, while not possessing intrinsic chaperone properties itself, is required for a particular chaperone to function.

Heat Shock
The exposure of cells or organisms to temperatures a few degrees above their normal growth temperature, widely used as an experimental model for inducing cellular stress.

HSP
Abbreviation for ''heat shock protein.'' HSPs are proteins that are induced *de novo* or are upregulated as a result of heat shock.

Molecular Chaperone
Proteins that assist other proteins to reach their final active conformation, but that are not themselves part of this final conformation.

Unfolded Protein
Any protein that is not in its fully folded state. This term encompasses a large range of possible states, from a protein that is nearly but not completely native to one that is a random coil.

Some proteins in the cell are needed to help other proteins reach their final active conformations: these are referred to as molecular chaperones. Molecular chaperones can be grouped into families by sequence similarity, and they act through a variety of mechanisms. They are found in all cell types and in most locations within the cell. Many are induced by stresses such as heat shock. This chapter will review the reasons why molecular chaperones are required in the cell, and then discuss each of the major families of molecular chaperones in turn, in terms of structure, mechanism of action, and cellular role. Most molecular chaperones act in networks with other chaperones, and some of these will be reviewed. Many molecular chaperones interact with a broad range of different substrates, but some are specific to particular proteins, and examples of these will be discussed.

1 The Definition of a Molecular Chaperone

The number and range of proteins now classified as molecular chaperones are very large, and a definition that encompasses all of them is likely to be so vague as to be uninformative. Molecular chaperones must, however, have two properties in order to be defined as such, which are as follows:

1. They must assist other molecules to reach their final active state, by blocking or reversing unfavorable events that would otherwise prevent this state from being reached.
2. They must not be part of the final active structure whose existence they have helped to create.

The name *molecular chaperone* was originally coined to refer to the protein nucleoplasmin, which is required for the correct assembly of nucleosomes, and the choice of the term ''chaperone'' is based on the conventional use of the word, to refer to a person who prevents inappropriate interactions from occurring that could hinder an otherwise desirable outcome. (The etymology of the word ''chaperone'' is of interest: it is derived from the French verb ''chaperonner,'' which means ''to protect.'' This, in turn, was originally derived from the Old French noun ''chaperon,'' which meant ''a protective hood''). The justification for this choice of name is that for biological molecules such as proteins, getting from the state where they are first synthesized to the state where they are finally active (folded, and in the correct cellular compartment) is a complex process during which many unfavorable interactions can take place. These, if they were allowed to occur, would drastically lower the efficiency with

which active biological material could be formed. Molecular chaperones prevent or reverse such interactions, which explains why they are so important for normal cellular function. Although the original chaperone (nucleoplasmin) is the key to chromatin assembly, the vast majority of chaperones are involved in protein folding and assembly, and it is only these that will be considered in this chapter.

In order for a given protein to be classified as a molecular chaperone, the chaperone activity of the protein should be experimentally demonstrable. Ideally, this demonstration would be made both *in vitro* and *in vivo*, through a combination of biochemical and genetic methods, but in practice this is not always feasible. The kinds of experiments that can demonstrate molecular chaperone activity are discussed below, in the sections on individual classes of molecular chaperone.

2 The Need for Molecular Chaperones: Protein Folding *In Vitro* and *In Vivo*

All life depends upon the ability of proteins to fold into specific conformations. An understanding of the process by which proteins succeed in folding from a linear chain of amino-acyl residues to a functioning tertiary or quaternary structure is thus central to an appreciation of all aspects of cell and organismal biology. The fact that this process occasionally goes wrong, and in doing so can lead to many pathological states, makes the need for such an understanding even more important. Most of the initial studies in this field were done using highly purified proteins, and these gave us many important insights into the essential features of protein folding. Studies of this nature are still continuing. More recently, however, it has been realized that protein folding inside the cell is a more complex process than that studied in the test tube, and many key discoveries have been made by looking at cellular protein folding in more detail. These include the discovery of molecular chaperones, which act in many ways to help proteins overcome some of the intrinsic problems caused by having to fold up in the complex internal environment of the cell. This initial section will thus briefly review our current understanding of protein folding both *in vitro* and *in vivo*, and will discuss in general terms some of the areas where molecular chaperones have been shown to be important or essential.

The earliest work in the area of protein folding was done by Anfinsen, who demonstrated that proteins will spontaneously adopt their native, active conformation in aqueous solution, thus proving that folded proteins are more thermodynamically stable than unfolded proteins. This conclusion was reached by taking purified proteins, denaturing them in suitable solvents that caused them to adopt an unfolded conformation, and then removing the denaturants and observing recovery of activity of the protein in question. No energy source is required in these types of experiments for proteins to refold, thus proving that the folded and active protein must be more stable than the unfolded form.

Although this was an elegant demonstration of the thermodynamically spontaneous nature of protein folding, it was subsequently pointed out by Levinthal that there was an apparent kinetic problem in protein folding. Because the number of possible conformations that can be adopted by a protein is very high indeed, and it takes a finite time for proteins to sample these different conformations,

it would in theory take, on an average, billions of years of searching through all the different conformational options for a given protein molecule to find the most stable conformation. It is known, however, that proteins can fold from the denatured state over a timescale of microseconds to seconds. To resolve this apparent paradox, Levinthal proposed that folding pathways exist, with a limited number of possible conformations existing along the pathways.

This view is still thought to be essentially correct, but the view of a folding pathway has been refined to that of an energy landscape. According to this view, the folding of a protein is analogous to the trajectory taken by a ball that is rolling around on a rubber sheet, which has been deformed by a heavy weight. The ball will eventually finish up at the bottom of the dip caused by the heavy weight; this is equivalent to the protein in its lowest energy conformation. The precise route that the ball takes to get to the bottom of the well depends on a number of factors, such as its initial starting point and the shape of the distorted sheet. Similarly, within a given population of proteins, some molecules may fold very rapidly and others more slowly. The fact that they all finish up in the same final conformation does not imply that they all have to follow precisely the same pathway to get there.

This view of protein folding can be further expanded to consider what events might lead to some proteins failing to reach a fully folded and active conformation. At least two such events can be envisaged, leading respectively to protein misfolding and to protein aggregation. In the case of protein misfolding, the polypeptide chain may reach a metastable state where it is indeed folded but has not reached its correct and active conformation, and cannot proceed to it on a biologically relevant timescale. In the case of protein aggregation, the protein may have formed interactions with other partially folded protein chains such that all these proteins are now held together but are inactive because they have not reached their fully folded states. Interestingly, aggregation appears to be specific in that, when it occurs in mixtures of proteins, similar or identical proteins will tend to aggregate with each other. Aggregation is particularly likely to be a problem where protein concentrations are high, since the likelihood of two proteins interacting with each other before they fold into the native state is greater. Aggregation is potentially a particularly serious problem for proteins, because the forces that drive protein folding (hydrophobic forces) are the same as the forces that lead to protein aggregation. It is also a problem inside the cell, where protein concentrations may be extremely high.

Aggregation and misfolding are not the only problems that may be faced by proteins as they fold within the cell (Fig. 1). Another difficulty for proteins is that many targeting events require proteins to cross membranes into different cellular compartments, and yet it is hard to envisage a more effective barrier to a folded protein than a lipid bilayer. In order to cross membranes, proteins generally need to be prevented from folding but protected from other folding proteins with which they might interact both before and after they have crossed the membrane. Proteins also often need to form interactions with a large array of cofactors and effectors, and may require the presence of these in order to adopt their active conformations. In this event, proteins would need to be synthesized but kept in a receptive state until the cofactor becomes available. Proteins on the secretory pathway in

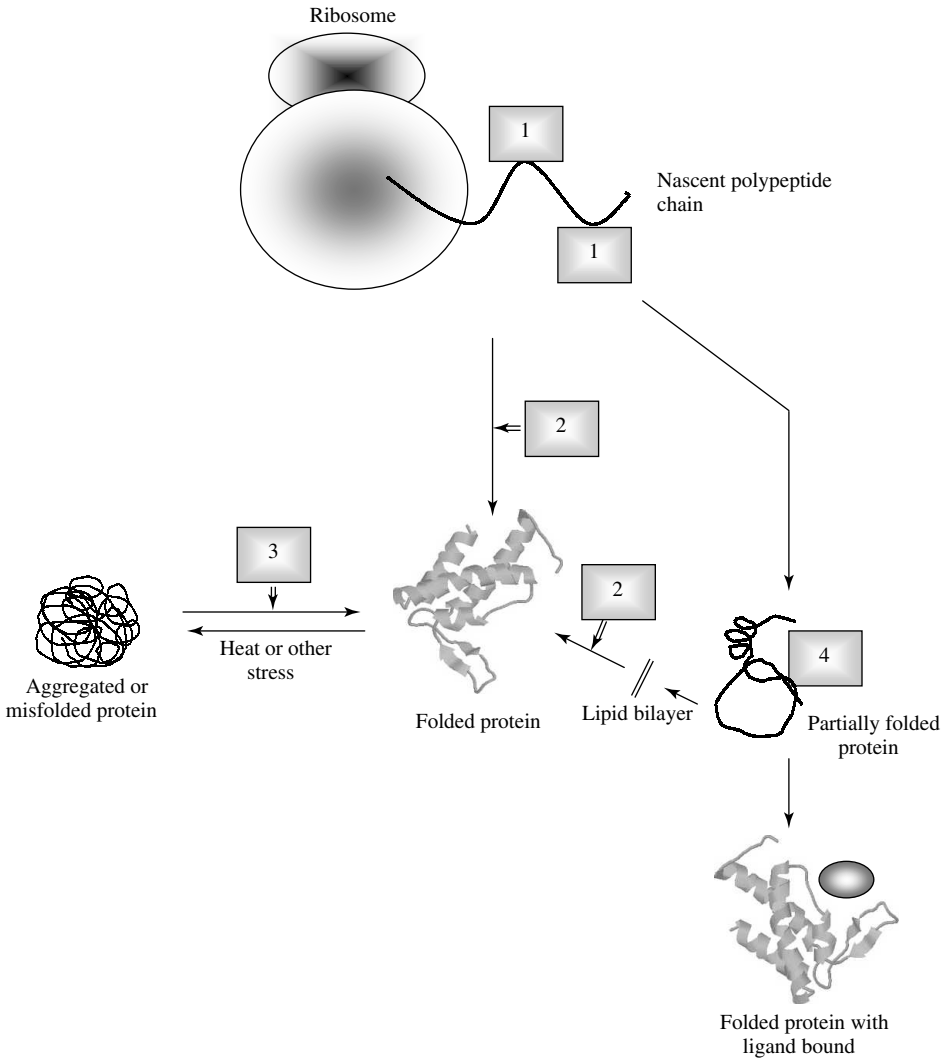

Fig. 1 The general roles of molecular chaperones. Molecular chaperones are involved in many different cellular processes, including protection of nascent proteins on the ribosome (1); folding of newly synthesized or newly membrane-translocated proteins (2); protection and refolding of misfolded, partially unfolded, or aggregated proteins (such as after heat shock (3); and maintenance of proteins in a partially unfolded state (4) for binding effectors or crossing membranes. Other roles are discussed further in the text.

eukaryotic cells have to be modified before leaving the endoplasmic reticulum (ER), and molecular chaperones play an important role here in quality control, ensuring that only those proteins with the correct modifications proceed further down the pathway. Finally, proteins are not particularly stable entities, and hence have a propensity to unfold under certain nonoptimal conditions such as a small

increase in temperature. Unfolding of proteins reintroduces all the potential problems of misfolding and aggregation that exist when the proteins are first synthesized.

Molecular chaperones are proteins that have evolved to deal with all these inherent barriers to the cell's need to have the right proteins in the right place in their active conformations. As later sections will describe, they have been shown to participate in all the examples given above, and in their absence many of these essential cellular functions cannot take place at all. Some chaperones appear to act predominantly by binding to and preventing the aggregation of proteins that have become unfolded; others are able to actively promote folding of proteins that otherwise cannot fold; and yet others can act on aggregated proteins to unfold them in order to allow them another opportunity to refold.

3 Classification of Molecular Chaperones

Molecular chaperones can be described in terms of their cellular locations, their mode of expression, their mode of action, and the proteins or other molecules upon which they act, but they are best classified in terms of sequence similarity. Chaperones that belong to a particular group defined thus turn out, unsurprisingly, to have similar structures and act on similar substrates through related mechanisms. The mechanisms of action and structures of the members of different groups are often quite distinct. The degree of sequence similarity within a group varies between different groups: some molecular chaperones are among the most highly conserved of all proteins, whereas others show very high heterogeneity between members of the same group. It must be remembered that sequence similarity alone is only an indicator of potential molecular chaperone activity, not proof of it, and that direct experimental evidence should always be sought to confirm whether or not a given protein is indeed acting as a chaperone.

The classification of molecular chaperones is complicated by a number of factors, some of which are as follows:

- First, certain proteins have been discovered that do not themselves act directly on protein substrates, but are required for the full chaperone reaction to take place. These are generally referred to as ''cochaperones,'' and as they are central to the chaperoning process they are usually discussed in the same context as molecular chaperones.
- Second, the fact that often proteins from the same chaperone family have been discovered and studied in different organisms or several different cellular locations at roughly the same time has led to a proliferation of names for proteins within a given family, which can be confusing.
- Third, many chaperones are heat-inducible, and as they were often first discovered by virtue of this property, they are referred to as heat shock proteins (HSPs). Unfortunately, this means many chaperone families are labeled as HSPs, even though not all the proteins within that family may be heat shock–inducible. An alternative approach is to use the names of the best studied member to label the group, but this is equally unsatisfactory as the name given to this protein may refer to

the phenotype through which the protein was first discovered, and which may be quite specific to a particular organism.
- Fourth, the name ''molecular chaperone'' is used in a very catholic sense to refer to any protein with the properties listed in Sect. 1 above, but these may range from extremely broad-spectrum chaperones, which act on a large range of substrates to those that have evolved to act with only one specific substrate.
- Fifth, many proteins are unfortunately described as molecular chaperones with only minimal supporting evidence from *in vitro* and *in vivo* studies.

The Table 1 is not intended to be comprehensive, but illustrates the major known families of molecular chaperones, together with the names of some of their better-studied members, their cellular locations, and a very brief description of their properties. The individual molecular chaperone families shown in the Table are discussed more fully in the following sections.

4
Mechanisms and Roles of the Major Molecular Chaperones

4.1
The Hsp60 Family

4.1.1 Introduction to the Hsp60 Family

The Hsp60 family is one of the best characterized of the molecular chaperone families. It is a large family consisting of highly similar proteins, all with a subunit molecular mass of around 60 kDa. Sequence comparisons have enabled the division of the Hsp60 family into two groups: Group I and Group II. The Group I proteins are found in nearly all bacteria, and also in mitochondria and chloroplasts. The Group II proteins are found in archaea, and in the eukaryotic cytosol. All these proteins have a remarkable multimeric structure: Group I proteins assemble into a ''double doughnut'' structure with seven subunits in each ring, and the Group II proteins assemble into a similar structure but with eight or nine subunits in each ring, depending on the particular protein and organism. Each ring encloses a cavity or cage. Proteins in the Hsp60 family are often referred to generically as ''chaperonins.''

4.1.2 Cellular Roles of the Hsp60 Family

The Group I family of the Hsp60 proteins has been the most intensively studied, particularly the protein from *Escherichia coli*, which is referred to as GroEL. Genetic evidence shows that these proteins are essential, both in prokaryotes and eukaryotes, and they are found in all organisms so far studied, with the exception of some mycoplasmas. They are present at fairly high levels in cells (*E. coli* is estimated to contain around 2000 GroEL complexes per cell under normal growth conditions) and are further induced by heat shock. All of them appear to require a cochaperone, called Hsp10, which is a smaller protein of typically around 10 kDa, which itself assembles into a ring with sevenfold symmetry. In *E. coli*, this protein is called GroES, and in *E. coli* and most other bacteria it is encoded in the same operon as the GroEL protein and is also essential.

If the levels of GroEL become too low to sustain cellular growth, or if a temperature-sensitive mutant is shifted to the nonpermissive temperature, a large subset of cellular proteins fails to fold

Tab. 1 Selected examples of the major chaperone families in the cell.

Name of family	*Prokaryotic examples*	*Eukaryotic examples*	*Cellular location*	*Known cochaperones*	*Cellular functions*
Hsp60	GroEL		Cytosol	GroES	Folding of a subset of newly synthesized proteins, folding of a subset of proteins damaged by heat shock and other stresses
	CCT (archaea)		Cytosol	GimC	Unknown; induced by heat shock
		Hsp60	Mitochondria	Hsp10	Import of proteins synthesized in cytosol, folding of proteins, protection against heat shock
		RuBP (rubisco subunit binding protein)	Chloroplasts	Cpn21	Import and folding of proteins synthesized in cytosol, and folding of proteins synthesized within chloroplasts, particularly the large subunit of rubisco
		CCT	Cytosol	GimC	Folding of actin and tubulin, folding of other cytosolic proteins
Hsp70 with Hsp40	DnaK/DnaJ		Cytosol	GrpE	Binding to nascent polypeptides, protection of protein from aggregation at high temperatures, dissolution of aggregates (with ClpB), regulation of heat shock response in *E. coli*
		Hsp70/Hsp40	Cytosol	Fes1, Bag1	Multiple proteins and multiple roles including binding of nascent proteins, protein import into organelles, uncoating of clathrin cages
		BiP/Sec63	ER	SLS1, BAP	Binding of incompletely folded secretory proteins, facilitating retrotranslocation to cytosol for proteasome degradation; note: several different proteins with J-domains interact with BiP
		mtHsp70/Mdj1	Mitochondria	Mt-GrpE	Import and folding of proteins, heat shock protection

(*continued overleaf*)

Tab. 1 (*continued*)

Name of family	*Prokaryotic examples*	*Eukaryotic examples*	*Cellular location*	*Known cochaperones*	*Cellular functions*
Hsp90	HtpG		Cytosol		Unknown, heat shock induced, but dispensable
		Hsp90	Cytosol	Hop, FKBP51, p23	Binding to proteins that require activation with ligand such as steroid hormone, protection against heat shock? Also buffers against genetic variation.
		Grp94	ER		Unknown, probably a role in quality control of protein transport
		TRAP1	Mitochondria		Unknown
Hsp100	ClpB		Cytosol		Works with DnaK to dissipate protein aggregates
		Hsp104	Cytosol		Works with Hsp70 to dissipate protein aggregates
sHSPs	IbpA, IbpB		Cytosol		Probably act to hold denatured proteins for other chaperones to refold
		Hsp25	Cytosol		Probably act to hold denatured proteins for other chaperones to refold
		α-B-crystallin	Eye lens		Keep eye lens proteins in solution
Redox chaperones	DsbA/DsbC		Periplasm		Respectively introduce and isomerize disulfide bonds; require DsbB and DsbD respectively to regenerate active forms
	Hsp33		Cytosol		Activated by oxidation, may protect proteins damaged by oxidation in cytosol
		Protein disulfide isomerase	ER		Introduce and isomerize disulfide bonds; requires Ero1 to regenerate active form
ER chaperones		Calnexin, calreticulin	ER		Act to prevent incorrectly glycosylated proteins from entering the secretory pathway

correctly. Coimmunoprecipitation experiments with antibodies against GroEL have also shown that a large number of different proteins (about 10–15% of all proteins in *E. coli*) bind to GroEL shortly after their synthesis is complete. It is thus thought that GroEL, together with GroES, acts to promote the correct folding of a subset of the proteins present in the bacterial cytosol that would otherwise not fold correctly. After heat shock, an increased association of proteins with GroEL is seen, and this implies that GroEL also acts to help refold proteins, which become wholly or partly denatured by an increase in temperature. The Hsp60 proteins present in mitochondria and chloroplasts are also involved in promoting the folding of some of the proteins that have been newly imported into the organelle after synthesis in the cytosol as well as some of those that are synthesized within the organelle. It was the recognition (in the late 1980s) of the unexpectedly high sequence homology between the chloroplast Hsp60 protein (the major function of which is the folding of the large subunit of rubisco, encoded by the chloroplast genome) and the *E. coli* GroEL protein (identified originally as a protein required for the folding of a component of bacteriophage lambda), which helped to galvanize research into the role and mechanism of action of these proteins.

The role of the Group II proteins is less clear. In archaea, the proteins are heat shock inducible, but not in eukaryotes. Archaea encode one, two, or three proteins in the Group II family, and these assemble into large complexes of two rings with eight- or ninefold symmetry. Eukaryotes encode eight proteins in the Group II family, which assemble into a double-ring complex with eight-fold symmetry. All eight genes are essential in yeast. The protein complex has been referred to variously as CCT, TRiC, and TCP-1. The principal role of this complex in eukaryotes appears to be the folding of the cytoskeletal proteins actin and tubulin, and genetic evidence shows that when the function of the CCT complex is compromised with conditional mutants, cells show disorganized actin, defects in morphogenesis and cell division, and acute sensitivity to microtubule-depolymerizing compounds. Although many other proteins are also substrates for the complex, the complete range of cellular substrates has yet to be defined. Moreover, actin and tubulin are not found in archaea, and the substrates for the archaeal Hsp60 proteins are completely unknown. The Group II Hsp60 proteins do not require a cofactor homologous to the Hsp10 protein used by the Group I proteins, but substrates are delivered to them by a totally unrelated chaperone called GimC or prefoldin, which again is found in both archaea and eukaryotes but not in bacteria.

4.1.3 Mechanisms of Action of the Hsp60 Family

The mechanism of action of the Group I proteins, as typified by the *E. coli* GroEL protein, has been very intensively studied, and yet there remain considerable uncertainties about exactly how the protein works. *In vitro* experiments show that if certain proteins are denatured (by chemical or heat treatment) and are then allowed to refold, the yield of refolded protein is very low, but can be increased to nearly 100% by incubation with GroEL, GroES, and ATP (Fig. 2). This process requires a complex reaction cycle, which is discussed more fully in the next section. During the reaction cycle, the unfolded protein is transiently bound in the cavity formed on one ring by the capping of the ring by the GroES protein. There are

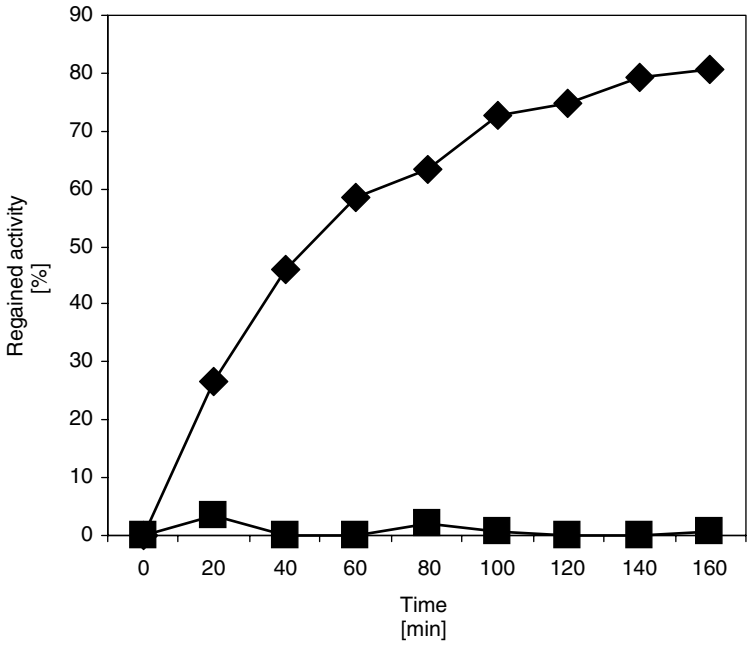

Fig. 2 Refolding of a denatured protein *in vitro* by GroEL, GroES, and ATP. In the example shown here, a substrate protein has been denatured in buffer using heat, and then returned to the temperature at which it is normally active. At suitable time points, the protein is assayed for regain of enzyme activity. The square symbols show the effect in buffer alone, and demonstrate that this particular substrate cannot effectively renature under the conditions shown. The diamond symbols show the effect of having GroEL, GroES, and ATP present in the buffer, with the GroEL and GroES at the same molar concentration as the substrate protein. As can be seen, this addition leads to restoration of roughly 80% of the initial activity of the protein.

at least three different models to explain how this process helps the protein to fold, and these are not mutually exclusive. The first (referred to sometimes as the ''Anfinsen cage'' model) proposes that the enclosed cavity simply provides a passive and protected environment where the protein can fold without interacting with other folding proteins with which it might otherwise aggregate. A refinement of this model (the ''assisted folding'' model) suggests that the environment of the cage is important, as the interior surface of the cage is rich in hydrophilic residues that tend to favor the burial of hydrophobic residues in the encapsulated substrate protein, thus accelerating folding. A third model (the ''iterative annealing'' model) suggests a very different role for GroEL. In this model, the principal role of GroEL is to *unfold* proteins that have become trapped in nonproductive misfolded states, and to redeliver them to the start of the protein folding pathway. It is quite possible that elements of all three models are correct, and that the extent to which any one applies varies with different substrate proteins. Further refinements to these

models may be required following recent demonstrations that GroEL can help fold some proteins that are too large to fit into the cavity of a single ring.

The mechanism of action of the Group II proteins is much less well understood. Actin and tubulin have both been shown to interact with specific subunits of the CCT complex (which are always present in the same order in the complex), and there is evidence that the substrates remain bound throughout the folding cycle, unlike the case in GroEL in which they are discharged into the cavity. It may be that the large domain movements of the complex that take place during the folding cycle act to force the bound unfolded protein into a more compact folded form.

4.1.4 Structure and Function of the Hsp60 Family

It is the remarkable structure of the Hsp60 proteins that has been in part responsible for the degree of interest that they have raised. Members of both the Group I and Group II families have been studied by different structural techniques, notably X-ray crystallography and cryoelectron microscopy, and more recently in the case of GroEL by NMR. Hsp60 proteins assemble into double-ring structures with several subunits in each ring; in the case of CCT from eukaryotes, the relative position of each of these subunits is unique, so that each always has the same neighbors. The individual subunits of proteins from both families consist of three distinct domains: an equatorial domain, which is responsible for the contacts between the two rings and for ATP-binding; a flexible intermediate domain; and an apical domain, which contains the region in which protein binding initially occurs. Moreover, both structures undergo large conformational changes as they pass through the different stages of the protein folding cycle. Again, it is the GroEL protein that is best understood.

The sequence of events that is thought to take place during the folding cycle of the GroEL protein is depicted in Fig. 3. Partially folded protein binds to one ring via a series of hydrophobic contacts with residues at the top of the apical domain. GroES binds to some of the same residues, and when it binds (which requires the presence of bound nucleotide) it displaces the bound peptide into the center of the cavity and simultaneously causes a very large conformational change in the ring to which it binds, the effect of which is to nearly double the size of the cavity. This structure slowly turns over the ATP, and until this reaction is complete, no protein or nucleotide can bind to the opposite ring. Once the ATP has been turned over to ADP, unfolded protein can bind to the opposite ring, followed by ATP and GroES, the net effect of which is to displace the bound substrate, GroES, and ADP, from the opposite ring to which binding first occurred. Thus, both rings are active in binding unfolded proteins, but do not do so at the same time as each other.

The models for action of GroEL discussed above can now be seen in the light of this mechanistic cycle. The Anfinsen cage and assisted folding models predict that the key event in the cycle is the encapsidation of the unfolded protein, which may lead to either the passive or active involvement of the cavity in promoting protein folding. The iterated annealing model sees the main event as being the large conformational change that takes place in the apical domains of GroEL as they move to bind GroES. It is proposed that these act to pull apart misfolded protein, before releasing it again at the start of the protein folding pathway.

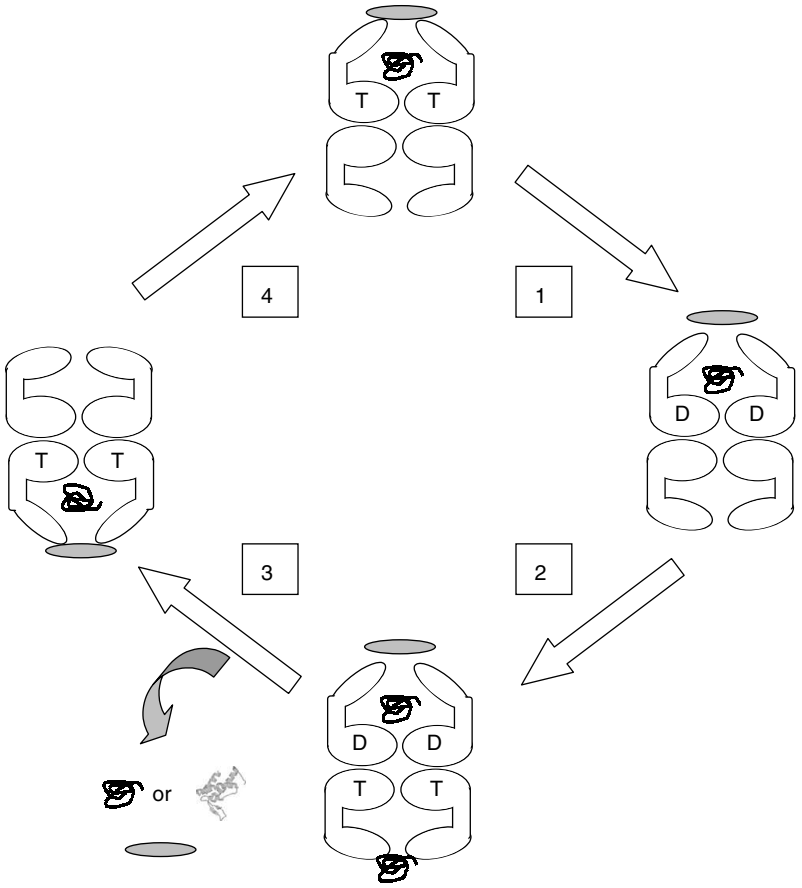

Fig. 3 The proposed reaction cycle of GroEL. GroEL is shown in cross-section, and GroES is shown as a filled ellipse. The complex at the apex of the cycle consists of substrate protein encapsidated in the top (cis) ring of the GroEL complex, which has the ATP (shown as T) bound, and is capped by GroES. The first reaction is the slow hydrolysis of ATP to ADP (reaction 1), which has the effect of weakening the GroES-GroEL interaction. During the time that this reaction occurs, folding of the protein may take place within the cavity. In reaction 2, ATP and another molecule of substrate protein bind to the bottom (trans) ring. This binding results in the release of GroES and ADP from the cis ring (reaction 3), and also the release of the bound substrate, which may now be either folded or still in a partially folded state. The new complex is now essentially the same as the starting one, as can be seen by flipping the complex (step 4) except that the former cis ring is the new trans ring, and vice versa.

The Group II proteins lack a functional GroES cochaperone, but in its place they possess a large helical protrusion at the top of the apical domain that forms a lid to the complex in a way similar to that formed by GroES. It is clear that large domain movements occur in the ATP-binding and hydrolysis cycle with the Group II proteins, but their relationship to the ability of this protein complex to promote the folding of proteins is not yet understood.

4.2 The Hsp70 Family

4.2.1 Introduction to the Hsp70 Family

The Hsp70 proteins comprise a large family, often with many representatives in a given organism (the yeast *Saccharomyces cerevisiae* has 14 Hsp70 homologs). They are found in all eubacteria, all eukaryotes, and most archaea. The Hsp70 proteins are all approximately 70 kDa in size, and show a high degree of sequence similarity. They act in concert with another family of chaperones, the Hsp40 proteins. These are more heterogeneous in size, and include both soluble and integral membrane proteins. All of the Hsp40 family members possess a particular domain (referred to as a J domain, named after DnaJ which is one of the *E. coli* homologs of this protein), which is key to their activity. In eukaryotic cells, both proteins are found in many different cellular environments, including the cytosol, nucleus, mitochondria, chloroplasts, and the lumen of the endoplasmic reticulum. They have a multiplicity of roles, all of which are related to their ability to bind to short stretches of hydrophobic residues in unfolded proteins. As with the Hsp60 proteins, their reaction cycle is driven by the binding and hydrolysis of ATP, but their mode of action appears to be very different. They utilize a wide variety of cochaperones and other factors, and are integrated into a network of interactions with other chaperones in the cell, as described below. Although originally described as heat shock proteins, some members of the family are synthesized constitutively and show no heat shock induction.

4.2.2 Cellular Roles of the Hsp70 Family

The Hsp70 proteins, together with the Hsp40 proteins, fulfill many functions inside the cell, as expected from the large number of homologs that can exist for these proteins in even a single organism. It is clear that not all of these functions have yet been defined. Some of the cytosolic members of the family are involved in binding nascent polypeptides as they emerge from the ribosome, probably thereby preventing them from folding prematurely before the whole chain has been synthesized. Other roles in the cytosol include the uncoating of clathrin from clathrin-coated vesicles, and the delivery of proteins to the mitochondrial and chloroplast import complexes. In the endoplasmic reticulum, the Hsp70 homolog Bip has a key role in ensuring that only correctly folded proteins are delivered to the secretory pathway, and that incorrectly folded proteins are returned to the cytosol for destruction by the proteasome. In the mitochondria and chloroplasts, the organellar homologs of the Hsp70 and Hsp40 proteins have a key role in the uptake of proteins that are synthesized in the cytosol and targeted to organelles, as well as in assisting the folding of proteins encoded by the organellar genomes.

That these roles vary in their importance can be seen from genetic studies. The main Hsp70 homolog in *E. coli*, DnaK, can be deleted, and although the resultant cells show reduced viability and no ability to grow at high or low temperatures, they are capable of growth at normal temperatures. The loss of viability is in part due to the fact that DnaK has a role in regulation of the heat shock response, and if the same deletion is made in *Bacillus subtilis*, an organism where DnaK does not have this role, the effect on viability is reduced. Two interpretations of these data are possible: one is that DnaK fulfills roles of relatively minor importance; the

other is that the roles of DnaK are so important that other proteins have evolved to back them up should DnaK become nonfunctional. At least one of the roles for DnaK, namely, that of binding proteins as they emerge from the ribosome, has been shown to fall into the latter category. Another chaperone, called trigger factor, also has this role, and although loss of either trigger factor or DnaK alone is not lethal, a double mutant is not viable under normal growth conditions (this is referred to as *synthetic lethality*). In yeast, some of the Hsp70 homologs are essential and others are not, and again synthetic lethality is seen for some combinations of mutants in different *hsp70* genes, proving that some of the cellular functions carried out by Hsp70 are essential. Trigger factor does not appear to have a homolog in eukaryotic cells, but another protein called NAC (nascent-polypeptide association complex) is thought to fulfill a similar role.

Another important role that has been demonstrated in *E. coli* and *S. cerevisiae* is not only the prevention of protein aggregation at heat shock temperatures but also the breaking down of any aggregates that may occur. For this activity, another chaperone is required: this is the protein referred to as ClpB in *E. coli* and Hsp104 in *S. cerevisiae*. The structure and precise mechanism of action of this chaperone is not known, but it clearly interacts specifically with Hsp70 in mediating protein disaggregation and subsequent refolding. This interaction is specific: yeast Hsp104 cannot substitute for *E. coli* ClpB. The role of ClpB will be considered further below (Sect. 5.2.1).

Hsp40 proteins share many properties with Hsp70 proteins. In all cases in which an Hsp70 protein is known to act, an Hsp40 partner protein is also involved.

4.2.3 Mechanisms of Action of the Hsp70 Family

Both Hsp70 and Hsp40 act by binding to short, exposed regions of predominantly hydrophobic stretches in unfolded proteins. Proteins bound to Hsp40 or Hsp70 do not appear to undergo any further folding, unlike the situation with the Hsp60 proteins, where the protein released from the complex may be in a very different conformation to the one that was first bound by it. Rather, it appears that the transient binding of these regions is enough to reduce the risk of their aggregation to other hydrophobic patches on proteins in the neighborhood. The importance of this is particularly obvious in those cases in which proteins have to be prevented from folding until the entire protein sequence is available to fold, namely, proteins being synthesized on ribosomes, and proteins being transported across membranes. Similarly, in the case of protein folding in the ER, proteins that still have regions exposed and are hence not ready for transport to the Golgi will bind to the Hsp70 homolog BiP. This protein has an ER retention signal at its C-terminus, and consequently is constantly cycled back to the ER from the early steps of the secretory pathway, together with any unfolded proteins that are bound to it.

Although the nature and role of binding of unfolded protein to the Hsp70 and Hsp40 proteins are different from those pertaining to the Hsp60 proteins, the reaction cycle has some similarities. In particular, as with the Hsp60 proteins, the reaction cycle relies upon the chaperones existing in two states, one with a high affinity for unfolded protein and the other with a low affinity, with the binding of nucleotide mediating the transition between those states. The reaction cycle, shown in Fig. 4 for the case of the *E.*

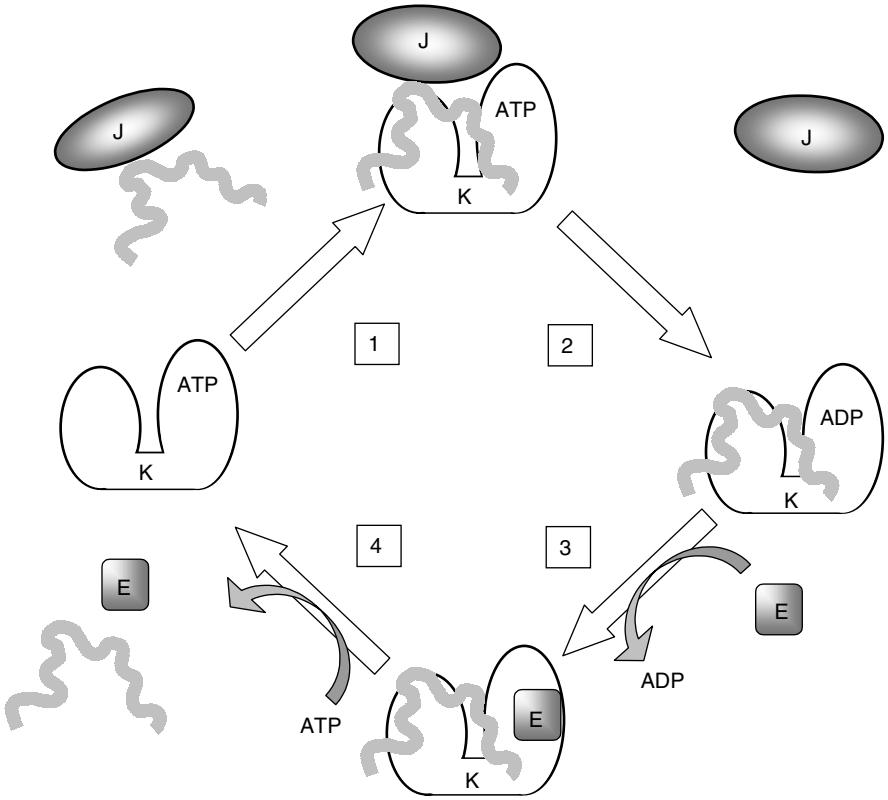

Fig. 4 The proposed DnaK/DnaJ/GrpE reaction cycle. Substrate protein is initially bound to DnaJ (shown as J), which delivers it to DnaK-ATP (step 1). The substrate is transferred to DnaK, and the presence of DnaJ stimulates the ATPase of DnaK to form a stable DnaK-ADP-substrate complex; DnaJ is probably lost at this point (step 2). This complex is stable until the cochaperone GrpE catalyzes the exchange of ADP for ATP, shown here as a two-step reaction where GrpE initially displaces bound ADP (step 3) and is in turn displaced by ATP (step 4). This causes DnaK to release the bound peptide, and the cycle can begin again. It is important to note that several molecules of DnaJ or DnaK may bind one protein. The reaction cycle is best characterized for the *E. coli* proteins shown; in eukaryotes, many different cofactors are involved with cycles involving Hsp70 homologs.

coli proteins DnaK and DnaJ, is thought to begin with the binding of unfolded protein to the Hsp40 partner, from where it is transferred to Hsp70, which is initially in a low-affinity binding state (with ATP bound). The formation of the Hsp70-Hsp40-unfolded protein complex stimulates the Hsp70 ATPase, and the ATP is hydrolyzed to ADP, which in turn has the effect of increasing the affinity of Hsp70 for the unfolded protein, but weakening it for Hsp40, which then dissociates. The resultant Hsp70-ADP-unfolded protein complex is now quite stable. In order for the unfolded protein to be discharged from its bound state, the ADP must be exchanged for ATP to lower the Hsp70 affinity for the unfolded protein. This exchange is a slow reaction but it is speeded up considerably by a cochaperone,

termed GrpE in *E. coli*, which catalyzes the exchange reaction and allows the cycle to be completed with the release of bound protein and the regeneration of the Hsp70-ATP form. GrpE homologs are found in archaea, mitochondria, and chloroplasts, while other proteins that catalyze the same kind of nucleotide exchange, such as Bag-1, are found in eukaryotes.

4.2.4 Structure and Function of the Hsp70/Hsp40 Family

Hsp70 is a two-domain protein, with one domain containing the ATP binding site and the other domain containing the peptide binding site. To date, no structure for the whole protein is available, but structures of the individual domains are known. The peptide binding domain has been crystallized with a bound peptide in place, and this structure shows that the peptide binds to a hydrophobic groove in the chaperone. The bound peptide is held in place by an α-helix, the position of which is thought to change depending on the nucleotide-binding state of the other domain, thus explaining how Hsp70 can change between a low-affinity and a high-affinity state depending on the presence of ATP. Hsp40 proteins can also bind peptides with high affinity, and structural studies on the conserved J domain shared by all these proteins show that again this binding is to a hydrophobic groove. The features that determine affinity of peptides for the grooves on these two proteins are essentially the same – consistent with the model that Hsp40 binds peptides (or, in the cell, stretches of unfolded protein with the appropriate amino acids present) first and then transfers them to Hsp70. The complete structural details of the complex formed by these two proteins are not known, however, so the fine details of this mechanism are not yet understood.

4.3 The Hsp90 Family

4.3.1 Introduction to the Hsp90 Family

The two chaperone families we have looked at so far have benefited from extensive study using simple prokaryotic systems, and many important features of the chaperones are conserved in both prokaryotic and eukaryotic organisms. The situation is somewhat different with the Hsp90 family, a family of well-conserved proteins of approximately 90 kDa, in that studies on prokaryotes show that loss of the *hsp90* gene does not in general produce a strong phenotype, whereas in eukaryotes the gene is essential. In eukaryotes, there are several genes encoding members of this family: the minimum number in complex organisms seems to be two very closely related forms in the cytosol, one in mitochondria, and one in the ER, although in *S. cerevisiae* the ER homolog is not present. Hsp90 proteins are very abundant, and are further induced by heat shock, and they have a rather broad range of cellular functions. Many of these are related to the ability of Hsp90 to hold proteins in a state that is not completely folded or active but which is competent to become so on the reception of a suitable signal.

4.3.2 Cellular Roles of the Hsp90 Family

Many substrates for eukaryotic Hsp90 proteins have been identified, and of these a large proportion are involved in some form of signaling. The best characterized of these are the steroid hormone receptors (SHRs), which are proteins that, when bound to their substrate (steroid hormones), enter the nucleus and stimulate the transcription of specific genes. Hsp90 holds these proteins in an inactive form until the hormone is available, whereupon

it binds to the SHR, which then dissociates from Hsp90, dimerizes, and enters the nucleus. Other proteins, such as the eIF-2α kinase, are bound by Hsp90 and released to become fully folded only after phosphorylation. The fact that Hsp90 is also a heat shock protein suggests that it may also have an important role in protecting cells, and it has been shown *in vitro* that it can bind to and prevent the aggregation of proteins under thermal stress.

The high levels and essential nature of cytosolic Hsp90 point to some other specialized function, and a clue as to what this might be has come from recent remarkable experiments that have shown that Hsp90 may be able to buffer potential phenotypic variation that is present, but not expressed, in all cells. When levels of Hsp90 activity are intentionally lowered, either genetically or by various external treatments, it is found in both plant and animal models that the degree of phenotypic variability seen is increased. Different alterations in phenotype are seen even between organisms that are genetically identical. Thus, it appears that Hsp90 may act to reduce ''noise'' that is present when organisms develop due to chance fluctuations in environmental conditions or small genetic differences, and this noise can be revealed when Hsp90 activity is compromised. It has even been speculated that this noise suppression may be a mechanism that has evolved to increase the amount of phenotypic variation present and expressed in a population at times of stress, where rapid evolution may be important for survival.

4.3.3 Mechanisms of Action of the Hsp90 Family

The way in which Hsp90 proteins bind to their substrates, and subsequently release them under the control of a suitable signal, is not well understood. What is clear is that the reaction mechanism in the cell is very distinct from those considered above, in that many more cellular cochaperones are involved. The folding cycle for SHRs has been particularly closely studied, and appears to begin with the partially folded SHR binding to Hsp70. Hsp70 can itself associate with a number of different cofactors *in vivo*, and one of these, referred to as Hop or Sti1 depending on the organism, mediates the binding of Hsp70 to Hsp90. The SHR is then transferred to Hsp90 and the Hsp70 and Hop components leave the complex. The SHR is at this stage still not competent to bind steroid hormone. Before it can become so, at least two other components associate with the Hsp90: a protein called p23, and one of a number of proteins that are peptidyl–prolyl cis–trans isomerases (PPIases). Both of these proteins have chaperone activities of their own, and the combined effect of all these proteins coming together is to alter the conformation of the bound SHR such that it can now bind steroid hormone. These reactions are shown in outline in Fig. 5.

A good deal of attention has focused on these latter stages in the binding cycle, as there was for some time a controversy about the role of ATP in the action of Hsp90. Hsp90 tested *in vitro* does not appear to require either binding or hydrolysis of ATP in order to act as a chaperone, but nevertheless contains an ATP binding site, deletion of which is lethal *in vivo*. It now appears that Hsp90 cannot bind to the PPIases or p23 until ATP is bound. As Hsp90 has a potential role in the cell cycle, promoting the folding of some of the kinases needed for cell cycle control, its inhibition in rapidly proliferating cells has been seen as a potential anticancer strategy. Some drugs

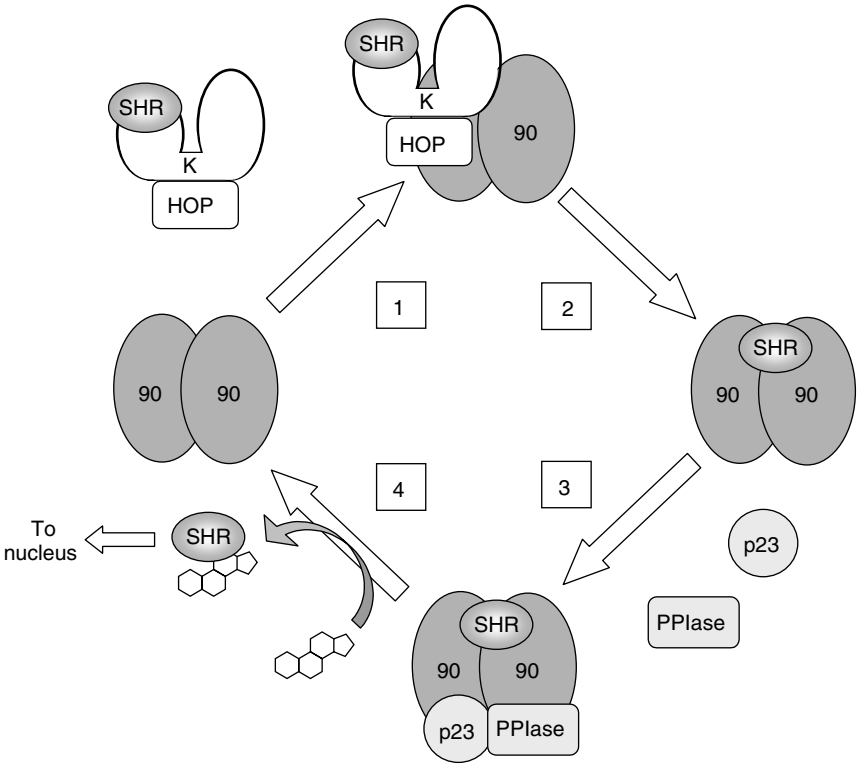

Fig. 5 Outline of the reaction cycle for Hsp90 binding to steroid hormone receptor (SHR). The SHR is delivered to the Hsp90 dimer by Hsp70 in a complex with Hop protein (step 1). SHR is transferred to Hsp90 (step 2), and p23 and PPIase associate (step 3). The precise order of reactions and the stoichiometry of the different proteins are uncertain. SHR can now bind to steroid hormone, which causes it to dissociate from Hsp90 and enter the nucleus to activate gene transcription (step 4).

that have been shown to inhibit Hsp90, in particular, the compound geldanamycin, appear to act as competitive inhibitors of ATP-binding, blocking the access of ATP and hence blocking the later stages in the Hsp90 reaction cycle.

4.3.4 Structure and Function of the Hsp90 Family

The structure of the complete Hsp90 protein is not known, but the structure of the N-terminal domain, which is the main site for binding of ATP, has been solved. As with other chaperones there is evidence of large conformational changes occurring on ATP-binding, but the structural details of these are unknown. Hsp90 is active as a dimer, with the dimerization domain in the C-terminal part of the protein, while the N-terminal regions may have a clamp activity, perhaps with the binding of a nucleotide causing the opening and closing of the clamp. Remarkably, it appears that there are likely to be peptide binding sites and ATP binding sites in both the N- and the C-terminal regions of the protein, but the functional significance of this is not understood.

4.4 The Small Heat Shock Proteins

4.4.1 Introduction to the Small Heat Shock Proteins

The small heat shock proteins (sHSPs) are a much more diverse group of chaperones than those considered above, and are correspondingly less characterized. They range in size from 15 kDa to greater than 40 kDa, and the degree of sequence similarity between them is lower than that for other chaperone families. All possess a conserved domain of approximately 90 amino-acyl residues near the C-terminal end, and all assemble into large oligomers, although again the sizes of these can vary considerably, even for a single sHSP. Organisms often contain numerous genes for sHSPs (plants are particularly abundant in them) and in eukaryotes they have been found in the cytosol, the ER lumen, and in mitochondria and chloroplasts.

4.4.2 Cellular Roles of sHSPs

The precise cellular role of the sHSPs has proven hard to pin down. Strains of *E. coli* or *S. cerevisiae* with all their sHSP genes deleted show very little significant phenotype unless the deletions are combined with other mutations, although in some organisms there is a reduction in thermotolerance when sHSPs are deleted. This lack of phenotype is a surprise, given that the sHSPs are often among the most strongly induced genes by heat shock. Overexpression of sHSPs has been shown to enhance thermotolerance in some cases, which does support the hypothesis that sHSPs have a role to play in survival of temperature stress. They are often found associated with protein aggregates, which have arisen either from the overexpression of proteins that failed to fold correctly, through heat stress or through disease states. There is also evidence that they may play a role in aspects of cytoskeletal and intermediate filament assembly.

A particularly interesting example of the sHSPs is the α-crystallin group of proteins, which are very abundant in the eye lens. Given that the eye lens is effectively a concentrated protein solution, which has to be kept clear for the lifetime of the organism (as cells laid down in fetal development remain in the center of the lens), the avoidance of protein aggregation is of particular importance. Loss of acuity of vision with age, and cataract formation, in particular, are associated with a breakdown in the ability of the α-crystallins to act effectively as chaperones. But defects in α-crystallin function have other consequences as well, showing that its importance is not limited to the eye lens. For example, the inherited disease desmin-related myopathy, which leads to muscle weakness, has been found in some cases to be associated with mutations in one of the α-crystallins, and probably results from defects in intermediate filament assembly.

4.4.3 Mechanism of Action of sHSPs

Despite the lack of a clear *in vivo* role, sHSPs have been demonstrated to have chaperone activity *in vitro*, in that they are able to bind and stabilize unfolded proteins and prevent their aggregation. The range of proteins that sHSPs can bind is very large, with no apparent limits on the size of the protein. There is no clear evidence that sHSPs are able to assist in folding *per se*, and the current view is that they act predominantly as reservoirs of unfolded protein, holding it in a nonaggregated state until conditions more favorable for folding are restored. Refolding of the bound proteins may occur either after the proteins are released into free solution, or

transferred to another chaperone system, such as the Hsp70/Hsp40 system. This is discussed further below, in Sect. 5.2.1. ATP is not required for any of this to occur, further supporting the idea that sHSPs are ''holders'' rather than ''folders.'' The way in which protein is discharged is not clear, but it may be related to changes in oligomerization and hydrophobicity that occur at different temperatures.

4.4.4 Structure and Function of sHSPs

The sHSPs form oligomers of variable size with fewer than 10 to more than 50 subunits. Moreover, when complexed with bound substrate proteins, their structure and degree of oligomerization may be significantly different from when they have no substrate bound. Several structures have been obtained of free sHSP, and all show oligomers formed roughly into a hollow sphere. The binding sites for unfolded proteins on the sHSPs have not been determined, and there is no detailed structural information for an sHSP-substrate complex.

5 Chaperones and Cellular Processes

A complete understanding of the role of chaperones in the cell is still some way off, but recent work has improved our understanding not only of the individual families of chaperones but also of how they interact with one another and in what way their activities are required for the survival and growth of healthy cells, both under normal and under stressed conditions. The following sections will examine some examples of chaperones and chaperone networks, which are employed for various different processes in the cell. This is not by any means a comprehensive list, but should give at least a flavor of the ways in which chaperones are involved in many different aspects of cell growth.

5.1 Chaperones and Redox Potential

Chaperones have a key role in enabling the cell to maintain active proteins under a variety of redox states, in at least two ways. First, they are directly involved in ensuring that proteins that require disulfide bonds for their activity form those bonds quickly and efficiently. Proteins that catalyze the reactions that make or break disulfide bonds in proteins are very important in maximizing the yield of active folded protein in cells, and many also can act as chaperones on substrates that lack cysteine residues. Second, chaperones exist that are activated by anomalous redox states to help chaperone the folding of those proteins that may themselves have become nonfunctional due to exposure to these states.

5.1.1 Disulfide Bond Formation and Isomerization in Prokaryotes and Eukaryotes

The formation of disulfide bonds in prokaryotes takes place in normal circumstances in the periplasm, the space between the inner and outer membranes in Gram-negative bacteria. (Gram-positive bacteria that have only a single membrane produce very few disulfide-bonded proteins, although interestingly they do express proteins capable of catalyzing disulfide bond formation). There is a significant difference between the redox states of the cytosol (which is highly reducing) and the periplasm (which is oxidizing), and it was originally thought that this difference was sufficient to allow disulfide bond formation to occur at a reasonable rate.

However, proteins have been identified in the periplasm of *E. coli* that catalyze both the formation and removal of disulfide bonds and thus speed up the rate at which proteins that contain such bonds are folded.

The two major proteins in *E. coli* involved in this process are both periplasmic proteins and are called DsbA and DsbC (Fig. 6). DsbA is a powerful oxidant, catalyzing the formation of disulfide bonds between cysteine residues in proteins that have been newly secreted to the periplasm, and itself becoming reduced as a consequence. Although bacteria lacking DsbA are viable, they show enhanced turnover of periplasmic proteins (owing to the presence of proteases in the periplasm that degrade unfolded proteins), lack of motility (owing to the failure of flagella to assemble), and high sensitivity to reducing agents. DsbA apparently binds proteins in a hydrophobic groove, rather analogous to the mechanism seen in some of the

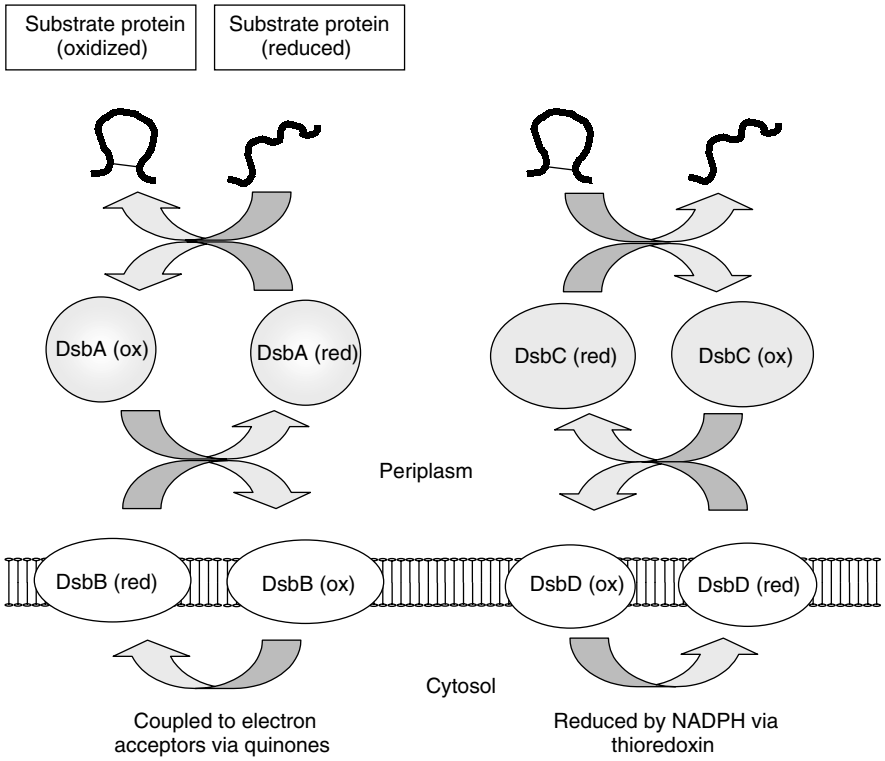

Fig. 6 Mode of action of some of the periplasmic Dsb proteins in *E. coli*. DsbA acts as an oxidase to introduce disulfide bonds into proteins with free thiols. In doing this, it is itself reduced, and must be reoxidized by oxidized DsbB, which in turn becomes reduced. DsbB becomes reoxidized by donating electrons to quinines, which flow to oxygen or other electron acceptors. DsbC in its reduced form acts either as a reductase (the net effect of which is to oxidize DsbC) or an isomerase (where no net redox reaction occurs). In the former capacity, it must be rereduced before regaining its activity; this is done by DsbD, which in turn derives its reducing power ultimately from cytosolic NADPH. Other Dsb proteins also exist in the periplasm of *E. coli* but have been omitted for clarity.

chaperones discussed above, but it is not significantly specific about which cysteines it oxidizes, so both correct and incorrect isomers of the same protein can be formed. The reduced DsbA must be reoxidized for further activity, a process that is mediated by a membrane protein called DsbB, which itself interacts directly with intermediates of the oxidative electron transport pathway to transfer the electrons liberated in disulfide bond formation to quinones and ultimately to either oxygen or, under anaerobic conditions, to other electron acceptors.

The formation of incorrect disulfide-bonded isomers by DsbA points to the need for an isomerase protein that can catalyze the breakage and reformation of disulfide bonds in proteins until the correct isomeric (and active) form is reached. In the *E. coli* periplasm, this role is performed by the protein DsbC. Like protein disulfide isomerase (PDI) (see below), this protein has an innate chaperone activity, in that it can recognize and bind unfolded proteins even when such proteins lack any cysteine residues. It seems likely that DsbC acts to bind incorrectly folded proteins, and then breaks the disulfides if they are present. Disulfides may then be reformed either by subsequent action of DsbA, or by spontaneous reoxidation of the reduced cysteines. In contrast to DsbA, therefore, DsbC must be maintained in a reduced state, and this is mediated by another membrane protein called DsbD. DsbD is in turn maintained in a reduced state by interacting with the cytosolic protein thioredoxin, which itself is kept reduced by metabolically generated NADPH.

The site for disulfide bond formation and isomerization in eukaryotes is the lumen of the endoplasmic reticulum. As is the case with bacteria, disulfide bond formation in newly imported proteins is an enzyme-catalyzed process, the enzyme in this case being protein disulfide isomerase. PDI is by far the most abundant chaperone in the ER. As with bacteria, a membrane protein (Ero1p) exists to restore the active (oxidized) state of PDI after the formation of disulfides has taken place. Reduced Ero1p in turn is reoxidized directly by oxygen, though its activity is also modulated by FAD. In addition to acting as an oxidase, PDI can shuffle the disulfide bonds in a protein after they have formed (hence its name), so it effectively combines the roles of DsbA and DsbC. As with DsbC, it is capable of showing chaperone activity, and so presumably can recognize proteins in which the disulfide bonds are not in the correct position for complete folding. The catalytic site and chaperone site are not the same and indeed are on different domains of the protein. This activity is more important in eukaryotic cells than in prokaryotic ones, as eukaryotic proteins have much larger numbers of disulfide bonds on average, and hence the possibility of forming incorrect disulfide bonds is correspondingly higher.

5.1.2 Hsp33: A Chaperone with a Redox Switch

An intriguing chaperone protein is found in *E. coli*, with homologs in many other species, which is heat shock induced but active only when oxidized. This protein, Hsp33 or HslO, binds very tightly to zinc ions when reduced, coordinating the zinc with four cysteine residues. Under relatively mild oxidizing conditions, the zinc is released and the cysteines form two disulfide bonds. This release causes a substantial change in the conformation of the protein, which significantly increases the amount of exposed hydrophobic area of the protein. In this state, Hsp33 acts as a ''holder'' rather like the sHSPs, and has

been shown to be capable of protecting a number of substrates from aggregation, whether induced by heat shock or by chemical denaturation. However, it has not yet been possible to demonstrate refolding of the bound protein substrates *in vitro*, implying that *in vivo* Hsp33 may interact either with one of the known chaperone proteins, or with a cofactor which is yet to be identified. The likely function of Hsp33 is protection of proteins, which may be particularly susceptible to oxidative damage *in vivo*, and the rapid activation of the chaperone activity of Hsp33 that takes place when the protein is oxidized, makes it an excellent first line of defense against oxidative stress, which can act until the cell has had time to induce a range of other defenses that will tend to act by restoring the normal redox potential of the cytosol.

5.2 Chaperone Networks and Protein Quality Control in the Cell

As research into molecular chaperones has progressed, it has moved to embrace considerations not only of how the members of individual chaperone families function, but also how they interact with other chaperone families within the cell. Much emphasis is now placed on understanding these interactions or networks. One such network has already been discussed briefly above: the interaction of Hsp70 and Hsp90 proteins in the activation of steroid hormone receptors. Chaperone networks have evolved to enable cells to maximize the efficiency with which they produce folded and active proteins, a process that faces two particular hurdles: the inefficiency implicit in the folding process itself (i.e. the extent to which proteins may finish up becoming misfolded or aggregated), and the fact that folding can be reversed by stresses such as heat shock. These networks also have to be integrated with the cell's mechanisms for disposing of proteins that are not functional. In the next two sections, we will look at two of the best understood of these: the system of protein quality control in the *E. coli* cytosol, and the system in the ER of eukaryotic cells. Neither of these, it must be emphasized, is yet completely characterized.

5.2.1 Chaperone Networks and Protein Quality Control in the *E. coli* Cytosol

It has already been pointed out in the text above that DnaK (one of the Hsp70 protein homologs in *E. coli*) and the unrelated protein trigger factor cooperate in chaperoning proteins that are still in the process of being synthesized on the ribosome. This is an essential process, and the trigger factor and DnaK must significantly overlap in the roles that they play in it, as demonstrated by the fact that loss of both genes together is lethal to the cell, whereas loss of either gene individually is not. It is likely that in normal cells, they act sequentially, with the trigger factor binding to proteins as they first emerge from the ribosome, and DnaK interacting with a subset of these later during synthesis.

Other interactions may exist between the DnaK and the GroEL chaperone systems. *In vitro* studies using purified substrate proteins have demonstrated that proteins can be transferred between these two systems effectively in either direction. Detailed *in vivo* evidence for a network between these two proteins is lacking, however, except inasmuch as a few proteins have been identified by coimmunoprecipitation experiments as being substrates of both systems.

More direct evidence exists to link the sHSPs of *E. coli* with the Hsp70 and Hsp60

major chaperone families. *In vitro* experiments show that unfolded proteins can be held in a nonaggregated but nonactive state bound to the sHSPs, and subsequently transferred to the DnaK and GroEL families for folding. *In vivo* experiments also support the existence of such interactions, although these interactions cannot be essential for viability as even under fairly extreme conditions, loss of the sHSPs from *E. coli* does not cause a severe phenotype. It may be that, as was seen in the case of trigger factor and DnaK, the ability for the cell to ''hold'' transiently unfolded proteins in a refoldable form is so important that more than one protein can act as the ''holder,'' and to date the other proteins that can do this have not been identified.

A third important interaction that exists between chaperones in *E. coli* is that between the Hsp70 protein DnaK and the Hsp100 protein, ClpB. Here, the evidence for an important interaction is much more compelling. It is clear both from *in vitro* and *in vivo* experiments that proteins aggregated by a stress such as heat shock can be disaggregated by the combined actions of DnaK and ClpB, and that the two proteins have very different roles in the process as they cannot substitute for each other. It is likely that ClpB acts upon protein aggregates first, altering their structure to a point where DnaK is able to promote their refolding. ClpB has thus been classified by some workers as an ''unfolder,'' and it is not able to assist the refolding of proteins on its own. Its mode of action is not yet understood, but it is a member of a large family of proteins called the AAA proteins, many of which have a major role in protein quality control. This leads us into the complex area of the overlap between protein refolding and protein degradation.

E. coli (and all other organisms) contains a large number of different proteases whose job it is to remove inactive or damaged proteins from the cell. This process becomes particularly important at high temperatures. A large number of these proteases are, along with ClpB, members of the AAA family of proteins, and some have features reminiscent of molecular chaperones. For example, several of them have an ATP-dependent ability to unfold proteins, and exist as ring-shaped oligomers (usually hexamers). For most of these, unfolding occurs as an essential step prior to degradation of the unfolded protein, either by another site on the same polypeptide that mediated the unfolding, or by another protein that acts in concert with the ''unfoldase.'' The unfoldase activity can, in some cases, give rise to a chaperone-like activity in *in vitro* experiments, although only in the case of ClpB does it appear to have a true role in helping proteins to refold *in vivo*. Degradation by these proteases is reduced by mutations in the DnaK and GroEL chaperone families, implying an interaction, indirect or direct, between the chaperone proteins and the proteases.

Thus, when proteins are unfolded in the *E. coli* cell, they may be captured by ''holders'' for subsequent refolding, or form aggregates that can be disaggregated by ClpB before refolding by DnaK (Fig. 7). In addition, they may be targeted to cellular proteases. Both these processes will help ensure that only active proteins are present in the cell, but the way the balance between them is achieved (i.e. what determines whether a given protein is degraded or refolded) is not known. Clearly, refolding is a preferential option to degradation if the cell is not to lose the investment in ATP that it has already made in producing the protein; equally clearly, refolding is not

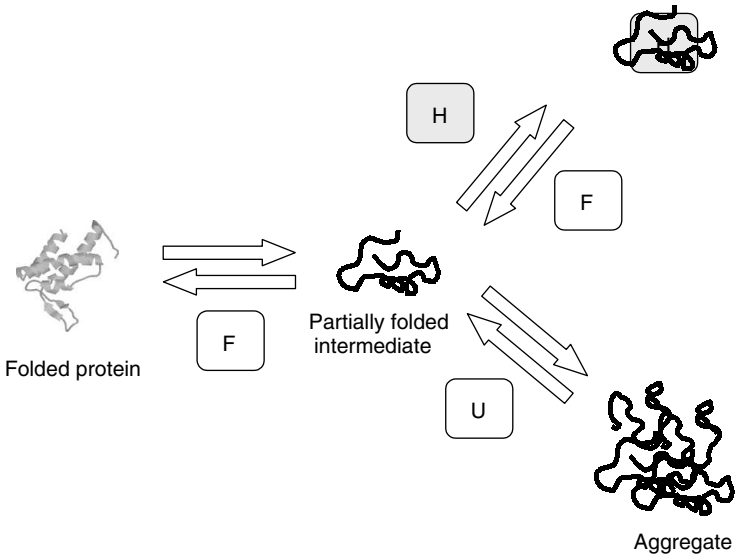

Fig. 7 Holders, folders, and unfolders in a chaperone network. A folded protein may become partially unfolded (for example, due to heat shock). It may refold spontaneously from this state, or may require the assistance of a ''folder'' chaperone (F), such as the GroEL/ES or DnaK/J systems. The partially unfolded state may interact further with other proteins in the same state to form an aggregate. This can be reversed by the action of an ''unfolder'' (such as ClpB). Alternatively, a ''holder'' chaperone (such as an sHSP) may hold the intermediate in a nonactive but nonaggregated state until a folder chaperone can refold it.

always an option, otherwise there would be no need for the cellular proteases to exist.

5.2.2 Protein Quality Control in the Endoplasmic Reticulum

The ER is of particular importance in the quality control of protein folding. It is the site for several important covalent modifications that are key to protein structure, including disulfide bond formation and glycosylation, and proteins pass through the ER en route to the plasma membrane and beyond, where they will be inaccessible to any further modification by chaperones. Thus, a substantial machinery is found within the ER to ensure that proteins are correctly folded and modified, and that leads to the degradation of those that are not. The components of this machinery include proteins that form and isomerize disulfide bonds, a key Hsp70 homolog, several proteins with DnaJ domains, and two proteins called calnexin and calreticulin. Other proteins with chaperone activity also exist in the ER (for example, an Hsp90 homolog called Grp94), although genetic evidence suggests they play a relatively minor role.

The Hsp70 protein homolog (also referred to as BiP, Grp78, and Kar2p) can be shown to associate with incompletely folded proteins using the same rules for binding as other members of the Hsp70 family. BiP has a C-terminal amino acid signal that retains it in the ER by cycles of retrieval from the Golgi body, and so any

protein that has bound to it is also kept in the ER until the sites that BiP recognizes are buried in the folded protein (or until the protein is retrotranslocated back to the cytosol for degradation, a process in which BiP also has a major role). Coimmunoprecipitation and cross-linking experiments have shown that BiP may bind early in the folding pathway, as do other Hsp70 homologs such as DnaK, but other studies support a role later during folding. Complexes recovered by such experiments often include other ER resident chaperones as well as BiP, supporting the model of a network of chaperone proteins acting in concert to promote correct folding. BiP can be acted upon by several different membrane proteins with DnaJ domains (all of which face the lumenal side of the membrane) and these may all be involved in BiP's various functions. As with classic Hsp40 proteins, they can act to stimulate the ATPase activity of their Hsp70 partner (BiP) and thus improve the efficiency of the cycling on and off the complex of partially folded protein. BiP is not the only chaperone in the ER that can interact with partially folded proteins: the PDI shares this property, and thus may be involved in retention of incorrectly folded proteins as well as in the formation and isomerization of disulfide bonds.

A more complex system exists to ensure that glycosylated proteins are in their correct conformation before further transport through the secretory pathway. Glycan chains are added at selected asparagine residues to proteins as they pass into the ER through the membrane. These chains have the formula Glc_3-Man_9-$(GlcNAc)_2$, where Glc is glucose, Man is mannose, and GlcNAc is *N*-acetyl-glucosamine. Shortly after these chains have been added, two of the terminal glucoses are clipped off by the enzymes glucosidase I and II, leaving a single glucose. The presence of this glucose makes the protein bind to one of the two chaperones calnexin and calreticulin, which are respectively transmembrane and lumenal proteins, thus preventing their further transport from the ER. In this state, they can also be acted upon by another PDI called ERp57, which itself binds to both calnexin and calreticulin. The final glucose residue on the bound substrate is removed by glucosidase II, which enables the protein's release from calnexin or calreticulin. If it is correctly folded, it will now exit the ER, but if it is incorrectly folded, a terminal glucose is added back to the protein by another enzyme (UDP-glucose:glycoprotein glucosyl transferase), which only acts on proteins that contain areas that are not folded, and the protein will be rebound by calnexin and calreticulin, thus reinitiating the cycle of protein folding on these chaperones. If after several cycles of this reaction the protein has still failed to fold correctly, it can be targeted for retrotranslocation and degradation in the cytosol.

5.3 Examples of Substrate-specific Chaperones

The chaperones that have been considered above are all examples of what are often referred to as ''broad-spectrum'' chaperones: that is, they have a range of different substrate proteins with which they interact. Not all chaperones are broad range, however; some interact with only one or a few substrates. There are many examples of these in the literature, two of which are considered here.

5.3.1 Hsp47 and Collagen Assembly

In addition to the various chaperones present in the ER and described in the

previous section, another chaperone protein called Hsp47 is also present. This protein is required for the chaperoning of one class of proteins only: the collagens. Collagens are the most abundant proteins in mammals, and the importance of the action of Hsp47 is shown by the fact that mice with both copies of the *hsp47* gene disrupted do not survive to term and show many abnormalities in collagen processing, which has numerous lethal effects on tissue integrity. How does Hsp47 act? To answer this question, we need to know something about collagen assembly.

Although there are large numbers of different types of collagen, they share certain common features. Collagen is synthesized as procollagen, which contains domains at both the N- and C-termini, which are removed in the formation of the mature collagen molecule. These N- and C-termini form globular domains while the rest of the procollagen molecule forms alpha-helices, three of which coil around each other to form the characteristic collagen triple helix. The alpha-helices consist of repeats of the motif G-X-Y, where Y is often proline (or hydroxyproline, formed in the ER from proline). This molecule is then transported to the Golgi body and ultimately to the cell surface, where the N- and C-terminal domains are removed and collagen triple helices become associated via unknown mechanisms into long fibrils. Hsp47 has been shown to bind to the triple-helical procollagen molecule, and this binding requires the presence of at least one arginine residue in the triple helix. The precise role of the Hsp47 binding is not yet clear, but one promising hypothesis is that it prevents the premature aggregation of procollagen molecules into larger fibrils, that would not be exportable from the ER. Intriguingly, Hsp47 has been shown to be capable of forming trimers, and one speculation is that it may form rings around the triple-helical procollagen molecules that could serve to prevent lateral aggregation with other procollagens.

5.3.2 PapD and the Assembly of Bacterial Pili

The interactions of chaperones and substrates generally lack the degree of specificity that is commonly associated with protein–protein interactions, and it is this lack of specificity that contributes to the broad range of substrates on which chaperones can act. However, the substrate-specific chaperones, such as Hsp47 above, must be able to recognize and act on particular substrates. In one group of proteins, the so-called PapD chaperones, the molecular basis for this recognition is understood, and this gives us useful insights into how such chaperones can act.

PapD chaperones are members of a superfamily of proteins, found in the periplasm of different bacteria, which are involved in the assembly of pili and other surface structures. This gives them considerable applied interest because pili and fimbrae play a major role in the attachment of bacteria to surfaces and in many cases this makes them important virulence factors in disease. More than 30 members of this superfamily are known. PapD is one of the best studied of these and was distinguished as the first chaperone (albeit one whose action is highly specific) for which a crystal structure was obtained.

Certain strains of *E. coli* produce so-called P pili, which are complex structures consisting of an adhesion protein (PapG) at the tip of the pilus, joined via an adaptor protein (PapF) to a string of subunits (of the PapE protein) in an open helical conformation, which in turn are linked by another adaptor protein (PapK) to another

string of subunits (PapA) in a helical cylinder. All these proteins are produced in the cytosol of *E. coli* and exported to the periplasm, and their subsequent assembly into a complete pilus requires the action of the PapD chaperone. In the absence of PapD, the various subunits are degraded by periplasmic proteases. PapD is not, however, part of the assembled pilus, and so it admirably fulfills the definition of a molecular chaperone.

Solving the structure of PapD, both alone and in complexes with proteins (PapK and PapE) whose folding it assists, has demonstrated how this chaperone works. The pilus subunits possess an Ig-fold, which normally consists of seven antiparallel beta sheets. In the pilus subunits, one of these helices is missing, which exposes a deep cleft in the protein. When the protein is in a complex with PapD, an N-terminal beta sheet from PapD fills the space that would normally be occupied by this missing region, thus stabilizing the protein by hiding the hydrophobic residues that would otherwise be exposed. This is referred to as ''donor strand complementation,'' since the completion of the stable Ig-fold is made possible by the ''donation'' of a β-strand from the chaperone. Indeed, it is likely to be the case that the folding of the individual pilus subunits only takes place in the presence of PapD. Given that this complex is now stabilized by the pilus-chaperone interaction, how does subsequent assembly of the pilus subunit into the growing pilus take place? This assembly happens by a process referred to as ''donor strand exchange,'' where the place occupied by the donated strand of the PapD chaperone is taken by a donated beta strand from the adjacent pilus subunit. This process takes place at an outer membrane pore made up of the protein PapC (sometimes referred to as an ''usher''). PapD, complexed to the various different pilus subunits, arrives at the PapC, and donor strand exchange takes place in order to add each new pilus subunit to those already there, which will thus be progressively extruded from the outer membrane of the cell. The order in which the subunits are found is presumably determined by the relative affinities of the different pilus subunits for each other, although this has not been directly proven. Recent results show that the role of PapD in this entire process is far from passive. PapD primes pilus subunits for assembly by holding the groove in an open conformation, which is closed during donor strand exchange, effectively locking the N-terminal extension of each adjacent pilus subunit in place on its neighbor. The interaction between PapD and its substrates is highly specific and, moreover, PapD can be said to be providing steric information required for the correct folding of these substrates.

6 Conclusion

This review has focused on the roles of molecular chaperones in the cell and described some instances of the way in which these roles can be understood in terms of the structures and reaction mechanisms of individual molecular chaperones. It must be emphasized that this is an area of research that has expanded very rapidly over the past decade and a half, and many aspects of molecular chaperone biology have had to be neglected in such a brief discussion. More attention is now being paid to the networks in which molecular chaperones operate and how these overlap with other key areas of the cell's activity,

particularly in the whole area of ''quality control'' – the optimization of protein folding activity under both normal and stressed conditions, and the rapid disposal of proteins which fail to meet the cell's requirements. Attention is also shifting to examining the roles of different chaperones in disease, most notably the protein-folding diseases such as the prion diseases, Alzheimer's, Parkinson's, and others. The possibility that a more complete understanding of the ways in which chaperones are involved in such diseases may lead to new therapies is an exciting one and a powerful incentive to further research in this field.

Acknowledgments

I am grateful to Professor R John Ellis, FRS, for his many useful comments on an earlier draft of this article.

Keywords

Bioluminescence
Light emission from a living organism.

Chemiluminescence
Light emission that occurs in chemical reactions as a result of the decay of chemiexcited species.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.
Copyright © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim.

Electrochemiluminescence
Light emission that occurs in electrochemical reactions.

Homogeneous Assay
An assay (e.g. immunoassay or nucleic acid hybridization assay) that does not require a separation step.

Immunoassay
An assay that uses specific antibodies or labeled antibodies to detect an antigen (the analyte).

Luciferase
The generic name for an enzyme that catalyzes a bioluminescent reaction.

Luciferin
The generic name for the substrate of a luciferase.

Luminometer
An instrument for detecting and measuring light emission.

Nucleic Acid Hybridization Assay
An assay that utilizes the specific recognition of a nucleic acid probe or labeled nucleic acid probe for a complementary sequence on the target nucleic acid.

Photoprotein
A tightly bound protein–luciferin complex that can be activated to produce light.

Bioluminescent (BL) and chemiluminescent (CL) reactions are used as analytical detection tools in immunoassay, protein and nucleic acid blotting, nucleic acid sequencing, and hybridization assays, and in reporter gene studies. In a BL or CL assay, the intensity or the total light emission is measured and related to the concentration of the unknown analyte. Light is measured quantitatively using a luminometer (photomultiplier tube or charge-coupled device) as a detector or qualitatively by means of photographic or X-ray film. The main advantages of these reactions are simplicity and an analytical sensitivity capable of obtaining results from minute amounts of analyte [attomole–zeptomole (10^{-18}–10^{-21} mol) range]. In immunoassay and nucleic acid hybridization tests, these reactions or their components are used in two ways: as labels and as detection systems for labels of other types (e.g. enzymes). Acridinium esters, acridinium sulfonyl carboxamides, isoluminol derivatives, the photoprotein aequorin, and luciferases from the firefly, marine bacteria, *Vargula* (formerly *Cypridina*), and *Renilla* are the principal luminescent labels. CL and BL detection schemes have been developed for assaying alkaline phosphatase, glucose oxidase, glucose 6-phosphate dehydrogenase, horseradish peroxidase, and xanthine oxidase labels. In addition, simple homogeneous assays are possible with CL acridinium ester and isoluminol labels, as well as with glucose 6-phosphate dehydrogenase labels. CL and BL reactions

can be adapted for the analysis of enzymes, substrates, cofactors, inhibitors, and metal ions, for the study of cellular processes (e.g. phagocytosis), and for toxicity testing. Luciferase genes (*luc, lux*) are now used as reporter genes, and the gene expression is quantitated by measuring the expressed luciferase in a BL assay.

1 Chemiluminescence

Chemiluminescence (CL) is the light emission produced in certain chemical reactions. Excited singlet-state molecules are formed in the reaction via the decomposition of high-energy intermediates such as 1,2-dioxetanes, dioxetanones, peroxides, or endoperoxides, which decay to the ground state, and some of the energy is released as light. The majority of CL reactions are oxidation reactions because these reactions can provide sufficiently energetic intermediates for light emission (e.g. 63.5 kcal/mol for blue light at 450 nm). One of the best-known CL reactions is the oxidation of luminol (5-amino-2,3-dihydro-1,4-phthalazinedione): the decay of singlet excited-state 3-aminophthalate molecules produces a blue CL at 425 nm. Generally, CL reactions are inefficient in aqueous media (CL quantum yield for luminol 0.01; i.e. 1% efficiency) but are improved in aprotic solvents (e.g. dimethyl sulfoxide). Figure 1 illustrates the diversity of compounds that undergo CL reactions (see http://www.shsu.edu/~chm_tgc/chemilumdir/chemiluminescence2.html for movies illustrating chemiluminescent reactions).

2 Bioluminescence

Bioluminescence (BL) is the light emitted from living organisms (''living light''). Many thousands of BL species have been identified (666 genera from 13 phylla), and the firefly (*Photinus pyralis*) is the best-known example (Table 1). Light emission (562 nm) is produced in an ATP-dependent oxidation of firefly luciferin, catalyzed by firefly luciferase (EC 1.13.12.7) (Fig. 2). This highly efficient reaction has a quantum yield approaching unity (100% efficiency). However, the majority of BL reactions are considerably less efficient than the firefly reaction. The color of bioluminescence emissions ranges from violet (395 nm) in the sea coral Thourella, through blue (470 nm) in the jellyfish Periphylla, green (550 nm) in the glow worm Lampyris, to red (705 nm) in the deep-sea fish Malacosteus. Most BL reactions involve an enzyme (a luciferase) and a substrate (a luciferin). Luciferases and luciferins from different BL organisms have different structures and compositions: for example, marine bacterial luciferase is a heterodimer (40 and 37 kDa), and the luciferin is a long-chain aldehyde, whereas Renilla luciferase is a 35 kDa monomer, and the luciferin is an imidopyridazine derivative. Some BL organisms utilize a precharged photoprotein instead of a luciferase; for example, in the jellyfish Aequorea, BL is due to the reaction of calcium ions with aequorin, a stable complex of apoaequorin and coelenterazine (a luciferin) that has been precharged with an oxidant (molecular oxygen). The BL emission is due to an energy transfer to green fluorescent protein (GFP) from excited-state coelenterate oxyluciferin.

3 Electrochemiluminescence

Chemical reactions at the surface of an electrode can also produce excited-state species that decay to the ground state and emit light (electrochemiluminescence). Ruthenium(II) tris(bipyridyl) undergoes an electrochemical reaction with tripropylamine to produce a strongly reducing tripropylamine radical and a strongly oxidizing ruthenium(III) species at the electrode surface (Fig. 3). These react to regenerate ruthenium tris(bipyridyl) in an electronically excited state that decays to the ground state and emits light at 620 nm. Suitably derivatized ruthenium(II) tris(bipyridyl) molecules are effective labels (detection limit 200 fmol/L) in nucleic acid assays of different types.

(a) Luminol X = H, Y = NH_2; isoluminol, X = NH_2, Y = H, (b) 8-hydroxy-7-phenyl-pyrido[3,4-d]pyridazine-1,4(2H, 3H) dione, (c) bis(2,4,6-trichlorophenyl) oxalate, (d) ozone–nitric oxide, (e) acridinium aryl ester, (f) CSPD, (g) siloxene, (h) lophine, and (i) lucigenin.

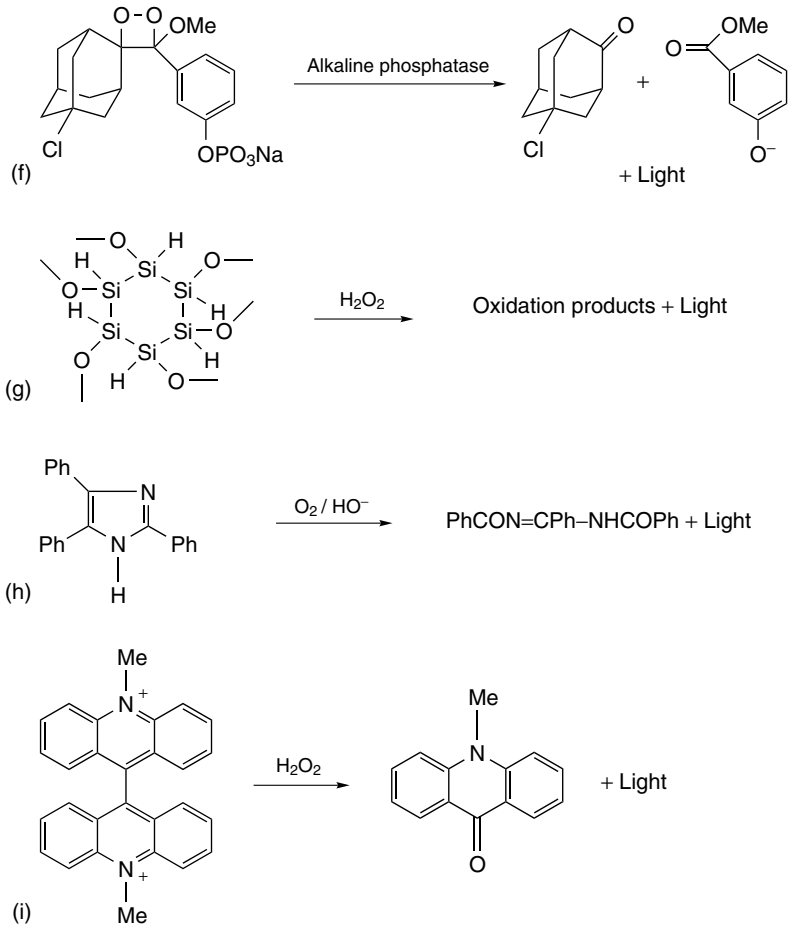

Fig. 1 (*Continued*).

4 Applications

Most assays simply involve mixing the sample with the appropriate CL or BL reagents and measuring or detecting the light emission. CL and BL reactions are sensitive and simple to perform; they utilize nonhazardous reagents, have a wide dynamic range (several orders of magnitude), and are usable in diverse applications (assays for proteins, DNA, RNA, enzymes, substrates, inhibitors, metal ions, and biomass) and in different assay formats (e.g. flow injection, liquid chromatography, extra-laboratory tests) (Table 2).

4.1 Measurement of Light Emission

Light can be measured quantitatively using a luminometer or qualitatively by means of photographic or X-ray film. Quantitative measurements are usually performed using a photomultiplier tube as the detector. This device can be operated in

the photon-counting mode or the less-sensitive photon-current mode. An alternative is to use a charge-coupled device (CCD) camera to image the light emission from two-dimensional sources. Reaction vessels of different geometries (microtiter plates, membranes) can be imaged and the images stored and manipulated to improve sensitivity via background subtraction techniques. Typically, a CCD detector divides the image into a 512×512 array of elements (pixels), but improved resolution can be achieved using sensors that divide the image into a 1024×1024 pixel array. The kinetics of the CL or BL light emission is a major consideration in light measurement. Rapid light emission (a flash of light) requires that

Tab. 2 Illustrative examples of applications of chemiluminescent and bioluminescent reactions.

Type of application or test	*Examples*
Antibodies	IgA, IgG, IgE, IgM
Antioxidants	Vitamin E
Biomass	Bacteriuria testing, enumeration of bacteria in milk, soil biomass, shelf-life dating, sperm viability
Chemosensitivity	Biocide assessment, tumor chemosensitivity
Drugs	Digoxin, methotrexate
Environmental	Phenolic herbicides, hygiene monitoring
Enzymes	Adenylate kinase, β-1,4-galactosyltransferase, creatine kinase, galactose 1-phosphate, *N*-acetyl-β-D-glucosaminidase, proteases
Gases	Nitric oxide, nitrogen dioxide, ozone, sulfur dioxide
Hormones	Follitropin, lutropin, thyrotropin, thyroxine, parathyrin
Lighting	Emergency and warning light, aerosols, and smoke
Metals	Ag, Bi, Ca, Ce, Co, Cr, Fe, Hg, K, Li, Mg, Mn, Ni, Os, Pb, Tb, Th, Tl, V, Zr
Oxidants	Hypobromite, hypochlorite, iodine, superoxide
Steroids	Estradiol, estriol, progesterone, testosterone
Substrates and cofactors	ADP, ATP, bile acids, ethanol, galactose, glucose, glucose 6-phosphate, glycerol, lactate, NADH, NADPH, oxaloacetate, phosphocreatine, pyruvate, sorbitol

the reaction be initiated in front of the photodetector using an injector. The wavelength of light emission is a further factor in selecting a detector. Photomultiplier tubes have a wavelength-dependent quantum efficiency for light detection and usually are most sensitive in the blue region (350–400 nm) and least sensitive in the red region (600 nm) of the spectrum.

4.2 Immunoassay, Blotting, and Nucleic Acid Hybridization Assays

The extreme sensitivity of CL and BL assays (detection limits in the attomole–zeptomole range: 10^{-18}–10^{-21} mol) has made them ideal for immunoassay and other applications (Table 3). CL and BL substances are

Tab. 3 Detection limits for labels used in immunoassay and nucleic acid hybridization assays

	Detection limits (zeptomoles: 10−21 mol)[a]	
Label	CL	BL

Isoluminol	50 000	
Xanthine oxidase	3 000	

CL, chemiluminescent assay; BL, bioluminescent assay.

effective alternatives to radioactive labels (^{32}P, ^{125}I), and generally, CL and BL reactions are superior to colorimetric and fluorescent reactions used to assay conventional enzyme labels.

4.2.1 Labels

Luminol, isoluminol, acridinium ester, acridinium sulfonyl carboxamide, firefly luciferase, marine bacterial luciferase, Renilla luciferase, Vargula luciferase, aequorin, and ruthenium(II) tris(bipyridyl) have all been tested as labels. Acridinium esters are one of the principal types of CL label in current use in immunoassay and hybridization assays. A rapid flash of light is produced by reacting the label with a mixture of H_2O_2 and NaOH. Nonseparation (homogeneous) nucleic acid assays can be formatted with an acridinium ester label, as in the ''hybridization protection assay.'' In this three-step assay, first the sample and an acridinium ester–labeled probe are incubated together. Next, the label on an unhybridized probe is hydrolyzed to a nonchemiluminescent product (probe bound to target nucleic acid is protected from hydrolysis), and finally a chemiluminescent signal is obtained from the acridinium ester label on the bound probe by treatment with oxidant in basic conditions (Fig. 4). The recombinant photoprotein aequorin is the most promising BL label. Light emission (rapid flash) is triggered by reacting the aequorin with calcium ions.

4.2.2 Detection Reactions

The two most popular enzyme labels, alkaline phosphatase and horseradish peroxidase, can be quantitated by a range of CL and BL reactions. These enzymes are used in several ways: as direct labels for nucleic acid, indirectly as avidin or streptavidin conjugates with biotin-labeled nucleic acids, or via antigen–antibody coupling, such as anti-digoxigenin conjugates with digoxigenin-labeled nucleic acids.

For alkaline phosphatase, the CL assay using adamantyl 1,2-dioxetane aryl phosphate substrates (e.g. AMPPD®, CSPD®) (Fig. 5) is convenient and very sensitive (detection limit, 1 zmol). In membrane-based assays (e.g. Western

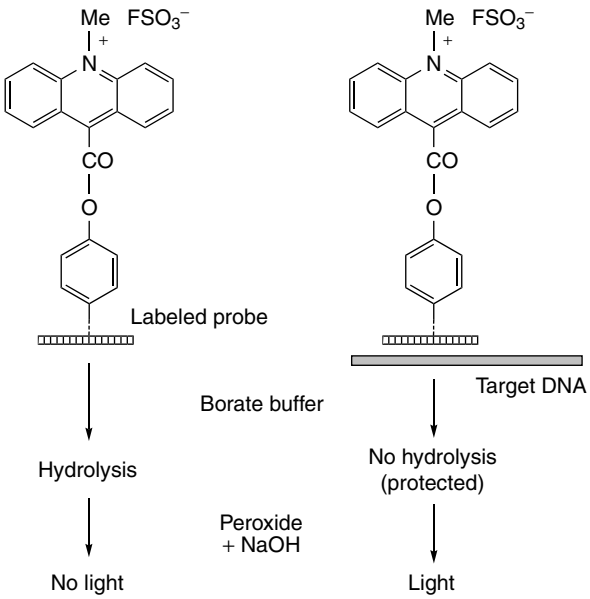

Fig. 4 Hybridization protection assay for detecting target nucleic acid (DNA) using a chemiluminescent acridinium ester label.

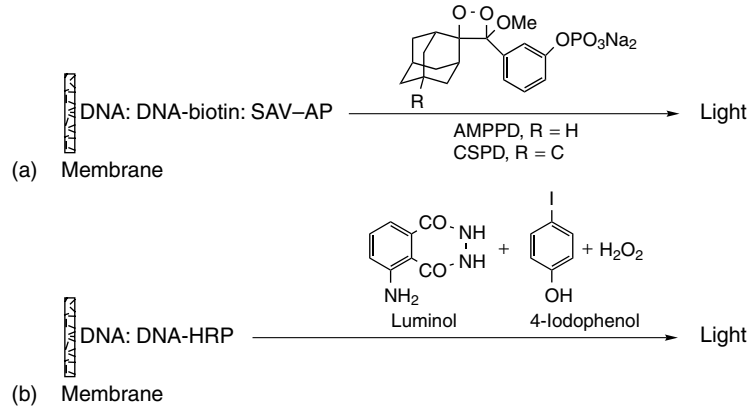

Fig. 5 Chemiluminescent detection of an alkaline phosphatase label using an adamantyl 1,2-dioxetane aryl phosphate (AMPPD®, CSPD®), and detection of a peroxidase label using the enhanced chemiluminescent reaction. AP, alkaline phosphatase; HRP, horseradish peroxidase; SAV, streptavidin.

blot, Southern blot), the nature of the membrane influences the CL signal from bound alkaline phosphatase. The surface of a nylon membrane acts as an enhancer of the CL signal because a dephosphorylated intermediate is sequestered in hydrophobic domains on the nylon. Similar improvements

in reaction kinetics, signal intensity, and signal-to-background ratio can be achieved both in solution and on membranes using certain water-soluble macromolecules [e.g. polyvinylbenzyl (benzyldimethylammonium) chloride]. Several highly sensitive sustained signal CL assays for horseradish peroxidase are available. These are based on (a) an acridan substrate that is converted by peroxidase into an unstable acridinium ester intermediate or (b) an enhanced chemiluminescent assay that uses luminol in conjunction with an enhancer molecule (e.g. 4-iodophenol, 4-hydroxycinnamic acid) (Fig. 5). In addition, sensitive CL or BL detection reactions of varying complexity are available for glucose oxidase, glucose 6-phosphate dehydrogenase, xanthine oxidase, and β-galactosidase labels (Table 4).

CL is also useful in DNA sequencing. For example, it is used to detect biotinylated DNA fragments transferred onto a membrane from a polyacrylamide sequencing gel. The biotin-labeled DNA is reacted with a streptavidin–alkaline phosphatase conjugate, and then the bound enzyme is detected using a 1,2-dioxetane substrate (e.g. CSPD®). Light emission from the membrane surface is imaged onto film or using a CCD camera as shown in Fig. 6.

4.3 Enzymes, Substrates, and Cofactors

The luminol, firefly luciferase, and marine bacterial luciferase reactions are sensitive indicator reactions for the production or consumption of peroxide, ATP, and NAD(P)H respectively. They can be coupled to other reactions involving oxidases, kinases, and dehydrogenases, and can be used to measure any component of the coupled reaction (enzyme, substrate, cofactor). Examples include the assays for alcohol and glucose, shown in Eqs. (1) and (2). Coimmobilization of a luciferase with other enzyme reagents improves the efficiency of the reaction because intermediates are effectively channeled to successive enzymes in the coupled enzyme system.

Biotinylated DNA sequencing reactions were loaded onto the gel in the following order (left to right): A, C, G, T. CL detection of bound streptavidin–alkaline phosphatase was performed using CSPD®. (Courtesy of Chris Martin, Tropix Inc., Bedford, MA.)

4.4 Reporter Genes

The chloramphenicol acetyltransferase gene (CAT) is used extensively as a reporter gene, but assay of the gene product is slow and requires the use of tritiated reagents.

$$\text{alcohol} + \text{NAD}^+ \xrightarrow{\text{alcohol dehydrogenase}} \text{acetaldehyde} + \text{NADH}$$

$$\text{NADH} + \text{FMN} \xrightarrow{\text{NAD(P)H : FMN oxidoreductase}} \text{NAD}^+ + \text{FMNH}_2$$

$$\text{FMNH}_2 + \text{decanal} + \text{O}_2 \xrightarrow{\text{marine bacterial luciferase}} \text{FMN} + \text{H}_2\text{O} + \text{decanoic acid} + \text{light} \quad (1)$$

$$\text{glucose} + \text{O}_2 \xrightarrow{\text{glucose oxidase}} \text{gluconolactone} + \text{H}_2\text{O}_2$$

$$\text{H}_2\text{O}_2 + \text{luminol} \xrightarrow{\text{peroxidase}} \text{3-aminophthalic acid} + \text{N}_2 + 2\text{H}_2\text{O} + \text{light} \quad (2)$$

The gene for firefly luciferase (*luc*) has been cloned and is an effective alternative to CAT as a reporter gene for studying transcriptional activity of cloned genomic sequences. Luciferase activity in transfected cells is measured by lysing the cells with a detergent (e.g. Triton X-100), adding ATP + Mg^{2+}, injecting firefly luciferin, and measuring the flash of light (detection

limit ca. 1×10^5 molecules). More recently, the luciferase detection reaction has been improved so that a constant light emission is obtained. This is achieved by adding to the assay mixture substances (e.g. coenzyme A, inorganic pyrophosphate, oxidized cytidine triphosphate) that minimize inhibition of the luciferase by oxyluciferin product molecules. The gene for Vargula luciferase, apoaequorin, and the fused marine bacterial luciferase *luxA* and *luxB* genes are also useful as reporter genes. Other alternatives include the CL assay (adamantyl 1,2-dioxetane aryl galactoside substrate, Fig. 7) of β-galactosidase expressed by the *lacZ* gene and the BL assay (firefly luciferin-*O*-phosphate substrate, Fig. 7) of the enzyme expressed by the alkaline phosphatase gene. BL genes are also effective for *in vivo* noninvasive imaging of whole organisms (e.g. plants, animals).

Membrane-permeable luciferin derivatives such as ethyl, hydroxyethyl, and hydroxypropyl esters (Fig. 7) permit nondestructive measurement of firefly luciferase reporter gene expression. These luciferin esters cross the cell membrane and react with intracellular esterases to produce luciferase. This enzyme then reacts with firefly luciferase to give light; the unreacted ester is not a substrate for the luciferase and does not contribute to the signal. Although not a BL reporter gene, the increasingly popular green fluorescent protein (GFP) is derived from a BL organism, the jellyfish *Aequorea victoria*. The advantage of this reporter is that the highly fluorescent expressed GFP can be detected directly using a suitable excitation light (ca. 470 nm) without the need to add reagent or disrupt the cells.

4.5 Rapid Microbiology

ATP (adenosine 5-triphosphate) is present in all living cells – a bacterium contains on average 1 fg of ATP – and measurement of ATP using the firefly luciferase reaction is a convenient means of enumerating cells, with a sensitivity of 10^5 colony-forming units per milliliter. The procedure entails first destruction of somatic ATP using the enzyme apyrase (EC 3.6.1.5), followed by lysis of intact cells with a detergent to release ATP, and finally BL assay of the released ATP using a mixture containing firefly luciferase, luciferin, and magnesium ions in the appropriate buffer.

4.6 Cellular Luminescence

Cellular CL is widely used for the study of phagocytosis. Activation of polymorphonuclear neutrophils by phagocytosable particles leads to the production of reactive oxygen species and weak chemiluminescence. Measurement of the weak CL is usually accomplished after enhancement by adding luminol or lucigenin.

4.7 Toxicity Testing

Drug toxicity and tumor chemosensitivity can be readily assessed via the bioluminescent ATP assay using the firefly luciferase reaction. Cell death or growth inhibition in the appropriate cell population that is due to the test drug is determined from the BL signal, which is proportional to the number of cells. Toxic substances can also be detected directly using luminescent bacteria. Contact with toxin inhibits light emission. When dark mutants of the BL marine bacteria *Photobacterium fischeri* are produced by mutagenesis with methyl methane sulfonate, for example, they react with mutagens, and the light-emitting properties of the bacterium are restored. Thus, a versatile and sensitive test for compounds with mutagenic properties is available.

Keywords

BAC (Bacterial Artificial Chromosomes)
A cloning vector for genomic DNA fragments up to 200 kb in length.

Contig Map
A map of the genome based on overlapping genomic clones, usually cloned in either YAC or BAC clones.

EST (Expressed sequence tag)
Expressed sequence tag, a single pass short read of complementary DNA (cDNA) that is generated from a transcribed region of the genome.

FISH
Fluorescence *in situ* hybridization.

Genetic Map
A map of the genome based on the linkage of genetic markers.

Marker
A gene or an anonymous segment of DNA that exists in multiple forms or alleles that can be used as a point of reference when mapping the inheritance of a specific chromosomal segment or a genetic phenotype.

Physical Map
A map of the genome determined directly by various methods including cytogenetics, radiation hybrid analysis and sequencing.

Reference Mapping Population
A pedigreed family used to construct a genetic linkage map, usually within a consortium of laboratories using the same DNA samples and information database.

RH Mapping Panel
A set of radiation hybrid clones used to construct a radiation hybrid (RH) physical map of the genome, usually within a consortium of laboratories using the same DNA samples and information database.

YAC (Yeast Artificial Chromosomes)
A cloning vector for genomic DNA fragments up to 1 Mb in length.

Elucidation of the chicken genome has wide-ranging implications for agriculture and biology. Genetic mapping in chickens has a long history. The recent use of DNA markers has allowed the construction of a consensus genetic map containing 51 linkage groups. Chickens have 39 pairs of chromosomes including microchromosomes. Thirty-two of the linkage groups have now been assigned to specific chromosomes using fluorescence *in situ* hybridization to reveal the location of specific genes on the cytogenetic map. A detailed BAC map of the entire chicken genome is being assembled and will be merged with a whole genome shotgun sequence. The comprehensive collection of chicken expressed sequence tag ESTs will be indispensable for annotating the physical map of the genome. The chicken genome is particularly well placed in the evolutionary tree to provide new insights into vertebrate gene and genome evolution during the past 300 million years.

1 Importance of Chicken Genomics

Chicken genomics have wide-ranging applications because the chicken is important both from agricultural and biological viewpoints. Chickens are arguably the most important source of animal protein for the human population worldwide. The chicken is also the most widely studied avian species and as such provides a warm-blooded vertebrate model. Their relative cheapness and high reproductive rate make them relatively accessible for genetic approaches. Furthermore, because there are both similarities and differences between chickens and humans, genetic comparisons should be particularly illuminating.

From the agricultural viewpoint, the main issues have been to do with features such as growth, meat quality, and egg production, and breeding programs have been selected for these different traits leading to broiler (meat-type) and layer strains. More recently, other traits such as the genetic basis of disease susceptibility and those associated with behavior are coming to the fore. Chickens provide excellent models for investigating quantitative trait loci for these and other parameters that may also be relevant to mammals and even humans.

A surprising number of fundamental biological discoveries have been made in chickens in areas as far apart as virology, immunology, and developmental biology. It was in chickens, for example, that it was first discovered that viruses could cause tumors and that B cells are a distinct class of lymphocytes. The immune system of chickens differs from that of mammals in that antibody diversification is based on the high frequency of gene conversion that occurs at immunoglobulin genes rather than on combinatorial joining, and this provides a novel perspective.

Because of the high frequency of gene conversion at chicken immunoglobulin genes, a chicken cell line, DT40, derived from a chicken bursal lymphoma has proved to be a powerful tool for assessing the function of genes that act cell-autonomously. Homologous recombination between host genomic and transfected DNA in DT40 cells is as efficient as in budding yeast. These cells have been used to probe gene function in several cell biological processes, not only in antibody diversification but also, for example,

in DNA recombination and repair and in signal transduction.

Chickens are also one of the main vertebrate models studied by developmental biologists. A particular advantage is that experimental manipulations can be carried out while the embryo is still in the egg. Classical manipulations consisted of ablating and/or transplanting cells and tissues within chick embryos to study cell–cell interactions and to assay cell determination. A wide range of manipulations is now possible, including the construction of chick/quail chimeras to study cell fate, the grafting of microcarrier beads releasing defined chemicals, such as growth factors and inhibitors, and genetic manipulations. DNA can be readily introduced into chick embryos using retroviral methods and/or electroporation, and these techniques have been used widely to overexpress genes at particular times and locations during embryonic development. A recent report suggests that RNAi should also be applicable to chick embryos opening up the possibility of using chick embryos for high throughput screening of vertebrate gene function.

2 Chicken Karyotype

The chicken genome has a haploid content of 1.2×10^9 bp of DNA and this is divided among 39 chromosomes including not only macrochromosomes, which are cytologically distinct, but also microchromosomes, which are found in all birds and in some reptiles. Chromosomes 1 to 8 are usually classified as macrochromosomes. The sex chromosomes are Z and W; in birds, unlike in mammals, it is the males that are homogametic (ZZ), while the females are heterogametic (ZW). A recent study suggests that the long-standing view that dosage compensation does not occur in birds is incorrect and that the majority of Z-linked genes are dosage compensated. The 30 chicken microchromosomes contain about one-third of the genomic DNA but originally it was not known whether this was genetically inert. A number of studies have now shown that the microchromosomes are in fact gene rich, with recent estimates suggesting that microchromosomes are twice as gene rich as macrochromosomes.

3 Maps of the Chicken Genome

Maps are used in everyday life to find objects (houses, streets, towns, etc.) in different countries around the world. In the same way, gene maps for a particular species tell us the chromosome location of a specific gene. The resolution of any map can vary from simple views of whole counties, highlighting major towns and cities, to high-resolution maps showing individual houses and streets. The same is true of gene maps, from which we may simply know the approximate physical location on a chromosome, as observed in a microscope (a cytogenetic map), or we may actually have the nucleotide sequence of the gene.

There are essentially two types of gene mapping methods: genetic (or genetic linkage) and physical mapping. In genetic mapping, the order and position of genes along specific chromosomes is deduced from the cosegregation of genetic markers in genetic pedigrees. Genes close together on the same chromosome tend to stay together and those further apart may be separated by genetic recombination. The result is an abstract map of each chromosome based on the frequency of

recombination. The genetic map has a direct colinear relationship with the physical map, where genes are mapped directly by a number of methods (FISH (fluorescence *in situ* hybridization), RH (radiation hybrid) mapping, contig building, and DNA sequencing) as shown in Fig. 1. The chicken has a long genome mapping history, starting almost 100 years ago with the pioneering work on Mendelian inheritance and sex determination. The first genetic linkage map for any domesticated animal was also in the chicken.

4 Genetic Linkage Maps

There are two requirements to construct a genetic linkage map: (1) pedigrees in which the cosegregation of genes can be followed and (2) polymorphic genetic markers. Markers must be polymorphic, that is, alternative forms must exist so that their inheritance can be followed among the different members of the pedigree. In the past, genetic markers were often based on differences in morphology (e.g. feather color) or blood groups, but today most are based on DNA-sequence variants. A sequence change may alter the function or activity of a gene; for example, a sequence difference may produce an altered protein product or may alter the expression of the gene. In many cases, such changes may also result in a change in phenotype (e.g. defects in growth hormone receptor gene result in sex-linked dwarfism). However, the most frequent changes used to create gene maps are in noncoding regions such

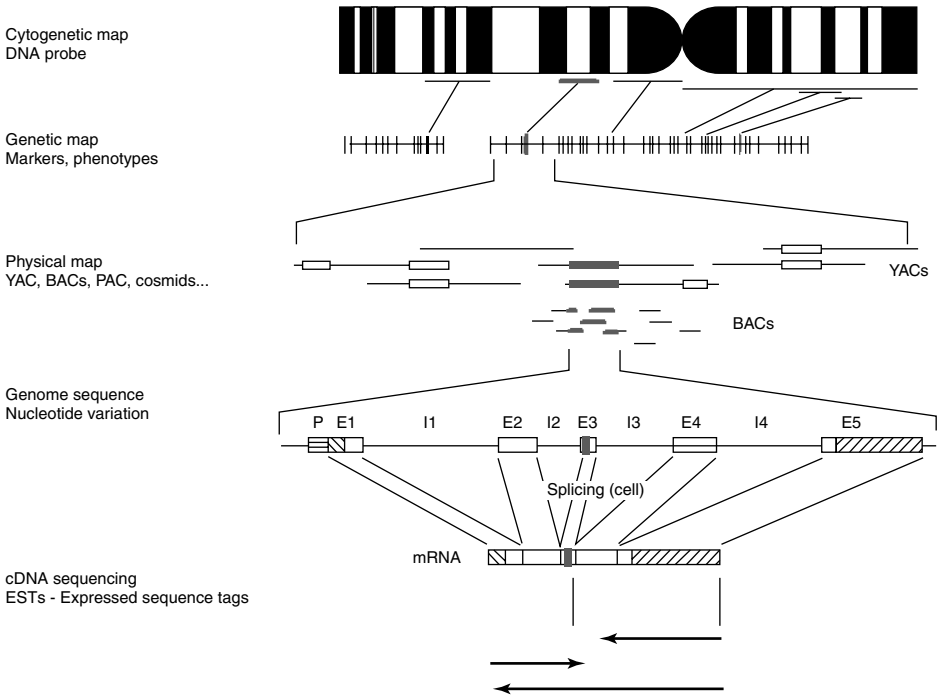

Fig. 1 Diagram showing relationship between genetic and physical maps and ESTs. Different methods of physical mapping are also illustrated.

as introns and may not have any effect on gene function. For example, a frequent genetic marker is based on variation in so-called *microsatellite sequences*. These are common and are based on simple sequence repeats (e.g. ACACACA. . .) that vary in length from individual to individual and may or may not be associated with a gene; they are therefore called *anonymous genetic markers*.

The first genetic linkage map for chickens based on DNA markers was published by Bumstead and Palyga in 1992 and was based on a cross between two partially inbred White Leghorn lines. Progress in creating a chicken genetic map (a consensus genetic map) accelerated when laboratories decided to pool efforts and concentrate on a few pedigrees (reference mapping families). The most fruitful pedigrees were the East Lansing and Wageningen populations. The East Lansing population consisted of only 52 backcross animals derived from a partially inbred jungle fowl and a highly inbred White Leghorn line. The resolution of this cross was low, between 5 and 7 cM. The Wageningen population consisted of 456 F_2 intercross animals derived from a cross between two broiler dam lines with origins from the White Plymouth Rock breed. With more progeny, the resolution of this cross was higher, about 1 cM. This is equivalent to about 300 kb or 5 to 10 genes. As an example, Fig. 2 shows the genetic map of chromosome 5 derived from the East Lansing and Wageningen reference mapping populations.

Early maps were based on various genetic markers (RFLP (restriction fragment length polymorphism), RAPD (randomly amplified polymorphic DNA), CR1-repeats and classical markers). Since then, most markers have been based on microsatellite sequences and AFLPs (amplified length fragment polymorphisms). Recently, more markers based on SNPs (single-nucleotide polymorphisms) have been used. Since many markers were in common between these various maps, it was possible to calculate a consensus map comprising 2012 loci and spanning 4000 cM. The consensus map still consists of 51 linkage groups, many probably representing the same microchromosome. So far, 32 of the linkage groups have been assigned to a specific chromosome by Griffin and all chromosomes now have a landmark probe.

5 Physical Maps

The resolution of physical mapping varies widely depending on the technique used, from 10 Mb in FISH mapping, 0.1 to 1 Mb in RH mapping, 0.1 to 1 Mb for BAC (bacterial artificial chromosome) and YAC (yeast artificial chromosome) physical maps, and to individual nucleotides in genome sequencing.

5.1 Cytogenetic Maps

The most reliable technique for *in situ* hybridization to reveal physical location on a chromosome has been FISH, where the DNA probe (e.g. a BAC clone) is labeled with a fluorescent dye. The location of the labeled probe is detected under the microscope after it has hybridized to its complementary DNA strand on a specific chromosome. Earlier experiments using radioactive *in situ* hybridization tended to be incorrect due to the technical challenges of the method. When combined with the availability of large genomic clones, FISH

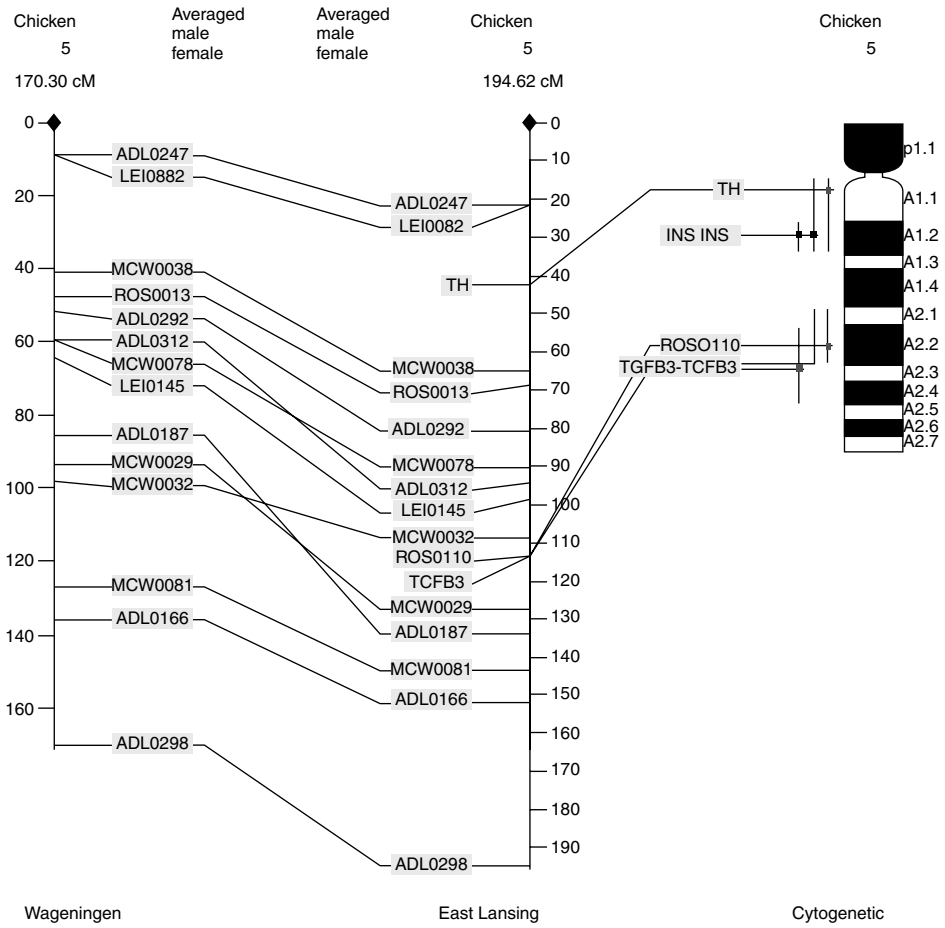

Fig. 2 Integration of genetic and physical maps of chromosome 5 (Arkdb-CHICK, June 2003).

has been a fast and simple method of mapping genes in recent years. The definition of a standard karyotype for the chicken by Ladjali-Mohammedi et al. has helped to exchange and compare data between different laboratories, in particular, for the larger chromosomes 1 to 8 and the sex chromosomes Z and W. Recent developments in the isolation of BAC clones and the isolation of individual microchromosomes have increased the possibility of a universal set of DNA or ''Landmark probes'' specific to each chromosome, including all 30 microchromosomes. In Fig. 3, chromosome paints derived from isolated chicken chromosomes have been used to identify homologous chromosomes in the turkey genome. To date, 218 genes have been assigned by FISH to a specific chromosome and 37 genes have been mapped to nonspecific microchromosomes. Through these experiments, genetic linkage maps have been assigned to specific chromosomes (e.g. Fig. 2 shows an integrated view of chromosome 5).

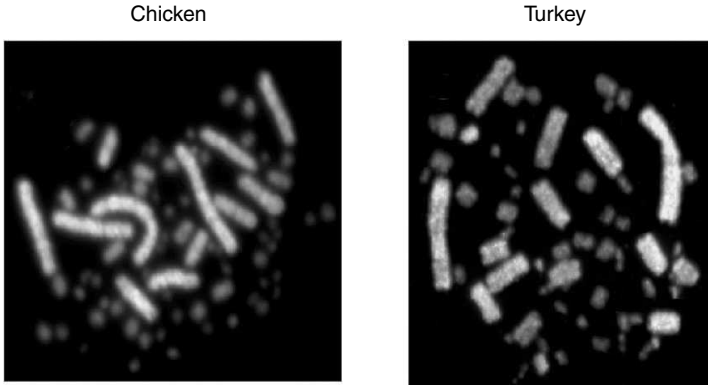

Fig. 3 Chromosome painting of turkey chromosomes with chromosome paints derived from chicken chromosomes 1 to 5, and the Z chromosome (kindly provided by Professor Johannes Wienberg). (See color plate p. xxi).

5.2 Radiation Hybrid Maps

A major limitation of genetic markers is the need to be polymorphic so that we can track their inheritance. About 10 years ago, the use of radiation hybrid mapping panels in humans and mice increased the rate of gene mapping significantly. In this method, the genome of the species to be mapped is fragmented by ionizing radiation. These DNA fragments are rescued by fusion with a host cell line to create panels of cells, each retaining a specific set of donor chromosomal fragments. Much like genetic mapping, genes close together on a specific chromosome will tend to be found in the same RH cell line. The frequency of coretention can be used to establish the order and distance between genes. In this method, since only the presence or absence of gene marker is required, there is no need to identify polymorphic markers; only a simple PCR test is required. In contrast to the success with other species, the construction of an RH panel in the chicken had met with limited success until recently. Early results for chromosome 7 mapped 77 loci, which are colinear with the corresponding genetic map. Currently, the chicken consortium are mapping over a thousand PCR-based anonymous and gene markers on this panel, which should prove to be an important tool to complement the BAC-based physical mapping.

5.3 Contig Maps

A contig map is constructed using a method that starts by fragmenting and cloning the genome in large segments of 100 to 1000 kb. Then various methods are used to identify overlapping genomic clones, and the data are finally assembled into a set of overlapping clones or contigs. Ideally, the process would end with a single contig for each chromosome, but usually the process defines hundreds of smaller contigs. The final number depends on the number of genomic clones analyzed (usually 100 000 clones) and the success rate for cloning difficult regions such as centromeres and telomeres.

Two types of large insert genomic libraries have been constructed in the chicken. The first was a YAC library that provided eightfold coverage of the chicken

genome. Such clones are difficult to maintain and analyze, so most contig-building projects nowadays use the simpler and more stable BAC system. In preparation for sequencing the chicken genome, many laboratories have constructed a number of BAC libraries with various enzyme combinations. The library by Crooijmans et al. was constructed with the restriction enzyme *Hind*III and contains 50 000 clones or fivefold coverage of the genome. Recently, three BAC libraries were constructed (*Hind*III, *Eco*RI, and *Bam*HI), each consisting of about 40 000 clones.

Methods used to create contigs vary and depend on using a simple and rapid method to identify a shared characteristic, such as the presence of a PCR product (STS or sequence tagged site), or more simply, an overlapping DNA fingerprint. These fingerprints can be generated in sophisticated ways (e.g. using AFLPs) or more simply, by restriction digests of the BAC clones (*Hind*III, *Bam*HI, *Eco*RI, etc.). Because the genomic inserts in these clones are large, many DNA fragments are observed for each clone after restriction digestion. The images are usually captured using imaging software and the results analyzed semiautomatically.

Currently, partial BAC contigs have been built for chicken chromosomes 10, 13, and 24, and when integrated with other data (sequence sampling data, genetic maps, RH maps, etc.), reveal gene maps of high resolution. Zhang et al.

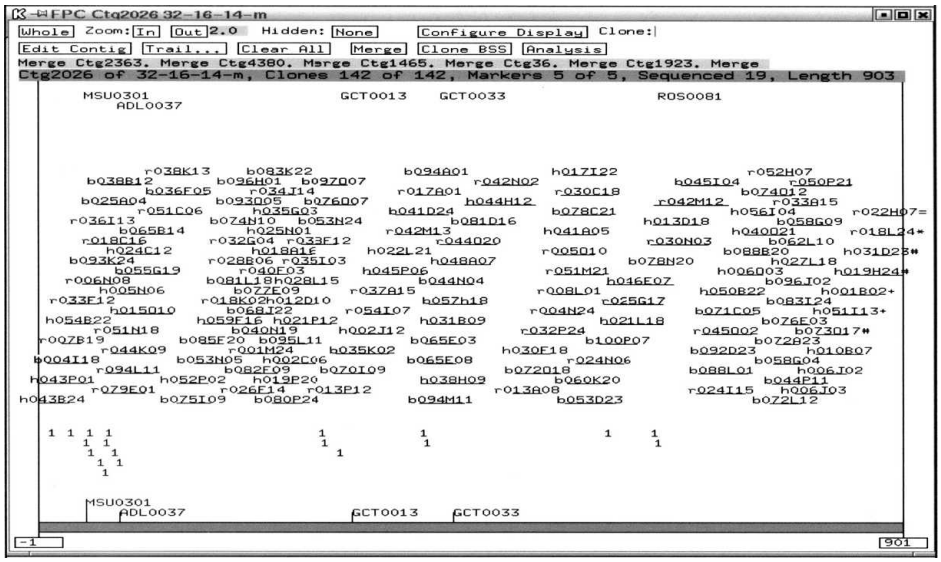

Fig. 4 Example of BAC contigs (ctg87, 1829 kb) for the chicken physical map. Example of chicken BAC contig anchored to the chromosome 1 genetic map of the chicken genome. This contig consists of 142 clones from three source BAC libraries, contains 903 unique fingerprint bands, and is estimated to span 4.01 Mb. The clones prefixed with h were from the HindIII BAC library, with b from the BamHI BAC library and with r from the EcoRI BAC library. The contig was anchored to the region around 361 cM of the chromosome 1 genetic map using five DNA markers – MSU0301, ADL0037, GCT0013, GCT0033, and ROS0081. The highlighted clones indicate the positive clones identified by DNA marker hybridization. (Reproduced by kind permission of Chengwei Ren, Mi-Kyung Lee, Bo Yan, Jerry B. Dodgon, and Hong-Bin Zhang).

(http://hbz.tamu.edu/) are fingerprinting over 100 000 chicken BAC clones (Fig. 4), which, when combined with the Wageningen BAC data, will result in a detailed BAC map of the entire chicken genome. This map will serve to order the whole genome shotgun (WGS) of the chicken genome.

6
Genome Sequencing

6.1
Sequence Assembly of the Chicken Genome

Owing to its interest as an important anchor species for evolutionary studies, there has been a rapid increase in genome sequencing of selected regions of the chicken genome. Such efforts will end with a nearly complete genome sequence in March 2004. Currently, there are 1811 entries in EMBL (June 2003) with information on gene structure in the chicken. In addition, there are a number of sequence sampling (BAC and cosmid clones) and BAC-end sequencing efforts. Of more interest are sequenced regions larger than 20 kb in length and since June 2003, the number in the nucleotide database is 133, of which 90% represent complete BAC clones. In general, these pilot genome-sequencing projects reveal that chicken genes share the same exon/intron structure as their mammalian orthologs. However, the genes in the chicken are more compact (2.5-fold), often with smaller introns. Also, the repeat content of the chicken is far less (10–15%) compared to mammals (50%), making WGS a practical option.

Extensive sequencing of large segments in the chicken has been limited: T-cell receptor beta-chain constant region (AF110982), T-cell receptor alpha chain constant region (U83833), beta-globin gene cluster (L17432), *MHC* complex (AL954802, AL023516), chemokine gene clusters, *SCL* locus, class II cytokine receptor gene cluster (AF082667), and to specific regions in the chicken orthologous to human chromosomes 7, 11, and 14. The general conclusions have been that the chicken regions tend to be two to three times smaller and that gene order is conserved over regions of at least 1 cM or 300 kb. The largest sequence is for a region orthologous to human chromosome 7q31.2. This sequence is 414 kb and covers 5 overlapping BAC clones. The order of the genes is identical (*TES, CAV1, MET, CAPZA2,* and *ST7*) to that found in the human genome, which covers a 1-Mb region. Another example is the 305-kb IGF2 region on chicken chromosome 5, also identical in gene order to its human counterpart (*IGF2, INS, TH, ASCL2,* and *CD81*).

The chicken genome-sequencing project will benefit from the experience gained from the human and mouse genome projects, and will include a mixture of targeted and whole genome sequencing. Currently, a physical map based on a 20-fold genome coverage of overlapping BAC clones is being assembled between laboratories at Washington University, Texas A&M, Michigan State University, and Wageningen University. This map will be integrated with other chicken mapping resources, including FISH mapped clones, genetic maps, and RH panels. Low sequence coverage of selected BAC clones, and BAC and Fosmid end sequences will be used to merge the BAC map with an eightfold whole genome shotgun. Preliminary assemblies based on 2.5 Mb of finished sequence have shown that this assembly approach should be very efficient

for the chicken. The high repeat content (~50%) in mammalian genomes has been a major problem with the WGS strategy; however, in the chicken, the repeat content is only 10 to 15%. This was shown dramatically in the repeat plots of finished genome sequences of human, mouse, and chicken. Also, more than 75% of WGS sequences from chicken BAC clones were contained in a single contig compared to only 25% in the mouse. The sequence will be based on a female (the heterogametic sex in chicken) inbred Jungle Fowl used to create the East Lansing genetic linkage map.

6.2 Comparative Sequencing and Identification of Conserved Regions

The chicken has often been used as an outgroup species in many evolutionary studies, in particular, in the study of the evolution of genes and genomes. Recently, there has been a rise in comparative genome analysis between long sequences in mammals (mostly human and mouse) and the chicken as a tool to identify conserved regions with the potential to function as regulatory sequences. This type of analysis began on a smaller scale in earlier gene sequencing studies in which conserved sequence motifs were found in both mammals and chicken. For example, it was identified that *NFκB, PEA1, PEA3,* and *C/EBP* transcription factor binding sites are associated with chicken inducible nitric-oxide synthase. It was shown that transcription binding sites in the 5′-flanking region of the *TGFB3* gene are conserved in chickens and humans. It was shown that the lens-preferred alphaA-crystallin gene contains a conserved stretch in the 5′-flanking region of the chicken and mouse genes. The 5′-half of this region has consensus binding sites for *AP-1* and other transcription factors. Furthermore, the mouse and chicken alphaA-crystallin genes are expressed with lens specificity using a similar assortment of transcription factors but with a different physical arrangement of their respective cis-elements within the promoter region.

A detailed study of the *SCL* locus compared 36 kb around the chicken locus with orthologous regions in human and mouse. In all the three species, the *SIL* and *MAP17* genes flanked the *SCL* gene. A detailed analysis also confirmed a number of previously characterized enhancer sequences and predicted a new enhancer 23-kb downstream of the *SCL* promoter start site. Another example is the comparison of the *alpha-globin* gene in a number of species (human, mouse, chicken, and Fugu) spanning 400 million years of evolution. In this study, several conserved motifs were identified in all the four species that suggested a common conserved function. A recent study on *SOX2* gene expression in the chick identified five functional-enhancer sequences in a 50-kb region flanking the chicken gene, after electroporation of embryos with various constructs. The exciting finding was that these functionally identified *SOX2* enhancers corresponded exactly to the extragenic sequence blocks conspicuously conserved between chicken and mammals, but which were not detected by sequence comparison among mammals. These large-scale studies require new bioinformatic tools such as *PipMaker*. An example of the type of analysis is shown in Fig. 5 in which a region on human chromosome 19p13.1 (contig NT_011295) is compared with orthologous regions on chicken and mouse chromosomes. The exciting thing about this is that the chick sequence is so well conserved

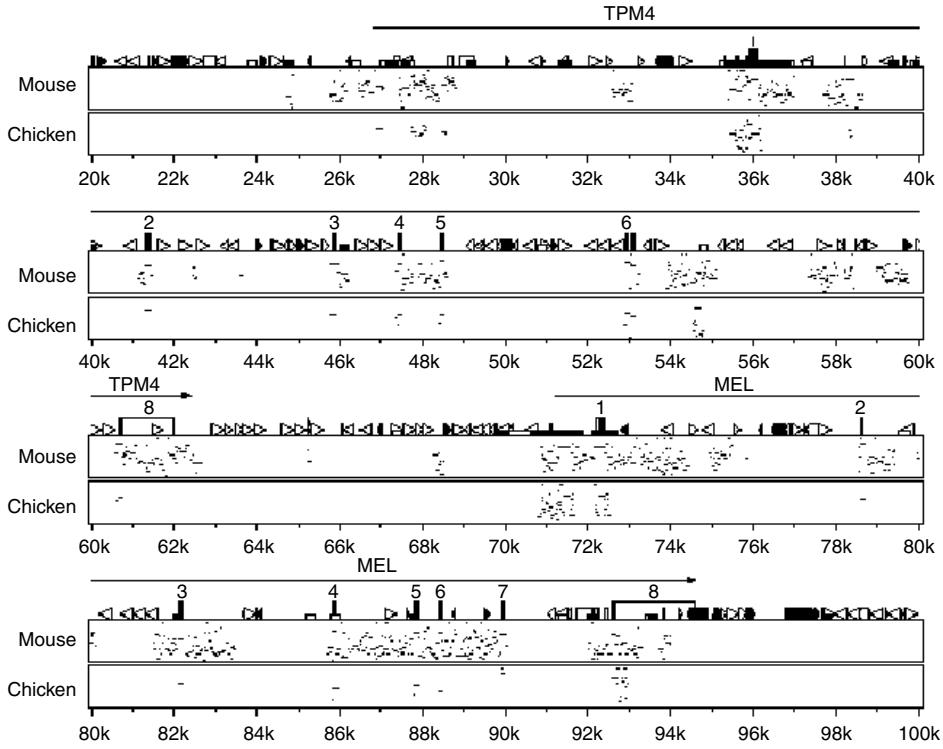

Fig. 5 Comparison of a segment of human chromosome 19p13.1 (contig NT_011295), with orthologous regions in the chicken and mouse genomes using the PipMaker program.

that most exons are visible as conserved sequences even at the nucleotide level.

7 ESTs

There is a large collection of chicken expressed sequence tags (ESTs) available (450 795 dbEST release 081503), which is an indispensable tool for annotating the physical map of the genome. EST programs include those carried out at the University of Delaware and the GSF (see www.chicken-genome.org for a complete summary). A large EST resource was funded in the United Kingdom by the BBSRC. This recent BBSRC project collected 340 000 ESTs generated from libraries taken from 21 different tissues, both adult and embryonic. Analysis of the data from this project gives an estimate of 35 000 chicken genes. Although the chicken genome is only about 40% of the size of the human genome, it is currently estimated to contain about the same number of genes. Furthermore, the microchromosomes (a third of the chicken genome) contain twice as many genes as the macrochromosomes. Thus, the chicken genome is compact.

Annotation of the EST data from the BBSRC project revealed that about 40% of clustered sequences have orthologs in known sequence databases. Furthermore, the chicken EST resource showed strong

matches to 90% of the human disease genes in the "morbid map" – a subset of human genes linked to known hereditary diseases. The EST resource is likely to contain additional chicken genes with, as yet, no known orthologs, or perhaps even genes that are avian specific. Ten thousand cDNAs from EST collections are currently being sequenced. These EST resources provide exciting opportunities for gene expression studies and for devising new tests for gene function using chick embryos.

8 Perspectives

During the past decade, the progress in chicken genomics has benefited from the sharing of data. ChickNET (http://dev.chicken-genome.org/) is one organization that tries to encourage this ethic. Using common resources, such as genetic mapping populations, genetic markers, physical probes, BAC libraries, cDNA and EST resources, RH mapping panels, microarrays, and the genome sequence, it will be possible to obtain different views of the chicken genome. A wealth of genome data for the chicken has already been produced using these resources and tools, and this will continue in the future. A number of genome mapping databases have been produced to store and manage such data. These databases include structural information, such as genetic maps, cytogenetic maps and banded karyotypes, RH maps, BAC and other clone-based maps, and the gene models based on EST sequences and other predictive tools. In addition, there will be the need to integrate more functional information, such as expression data (ESTs, *in situ* hybridization, etc.), mapping of genetic mutations, complex traits (QTL, Quantitative Trait Loci mapping) and phenotype using other tools (e.g. *RNAi*). Finally, such a genome view of the chicken needs to be compared and integrated with the views on other genomes, such as human, fish, and so on.

Keywords

Genetic Distance
An estimate of the amount of nucleotide substitutions between species. Genetic distance serves as a measure of the time elapsed since two species last shared a common ancestor.

Great Apes
Collective name for the orangutans (*Pongo pygmaeus*) from Borneo and Sumatra and for the African apes: chimpanzees (*Pan troglodytes*), bonobos (*Pan paniscus*), and gorillas (*Gorilla gorilla*).

Lineage Sorting
The distribution of alleles to the daughter populations upon a split of the ancestral population, for example, during speciation.

Monophyly
A group of species in a phylogenetic tree is monophyletic if all included species are descendants from a common ancestor to which no other species outside the group can be traced. Monophyletic groups are also referred to as clades or branches of a phylogenetic tree.

Phenotype
The complete set of organizational properties of an individual. It resembles the expressed information encoded in the genotype.

Phylogeny
A hypothesis about the evolutionary relationships of species expressed in a tree. All parts of a phylogenetic tree are inferred except the tips, which represent extant species or fossil remains.

On the basis of comparative molecular studies, chimpanzees are the closest living relatives of humans. On the level of their genomes, this is reflected in a nearly identical chromosomal organization and an average DNA sequence difference only about 10 times higher than that between any two humans. This renders the comparison of chimpanzees and humans, and the resulting catalog of their genetic differences, suitable to gain relevant insights into human evolution and human disease. The collection of genetic differences between both species as a whole comprises an ideal data set to analyze how DNA sequences change over time on a high-resolution scale. Of further interest are those differences that are located in the functional regions of the genome. They form the genetic basis of the distinct biological properties of humans and chimpanzees and thus might bear an answer to the question "What makes us human?" More practically, these differences provide access to the molecular factors that account for the different disease spectra in humans and chimpanzees, and might, therefore, open up new therapeutic approaches to fight human disease.

The relevance of chimpanzees as a subject in evolutionary and biomedical research is obvious. However, their close relationship to humans demands ethical guidelines that clearly distinguish chimpanzees from common genetic model organisms in laboratory research.

1 Human and Great Ape Phylogeny

For more than a century, scientists have been busy reconstructing the phylogenetic relationship of humans and the great apes. On the basis of the presence of shared morphological or molecular characters, individual species can be grouped to clades of an evolutionary tree. At the end of the nineteenth century, morphological evidence led to the generally accepted view that the great apes together with gibbons (*Hylobates* sp. and *Symphalangus* sp.) and humans share a common ancestor from which no other living organism descended. In phylogenetic terms, they represent the monophyletic group of hominoids within the primates (Fig. 1).

While this view has remained unchallenged since then, the relative order in which the lineages to the individual hominoid species emerged – often referred to as the "branching order" – provoked intense debate. From the shared consensus that the gibbon lineage diverged first, several competing hypotheses were proposed concerning the branching order of the remaining species. According to one favored scenario, the African apes (chimpanzees, bonobos, and gorillas) branched off second, allying humans with orangutans (Fig. 2a). An alternative view already taken by Darwin and Huxley positions the African apes closer to humans than the orangutans. Obviously, this hypothesis requires a further decision whether the closest relatives of chimpanzees and bonobos are the gorillas – as most morphologists believed – (Fig. 2b) or whether either of the species is closer to humans (Fig. 2c, d). The limited number of phylogenetic informative morphological characters as well as their sometimes

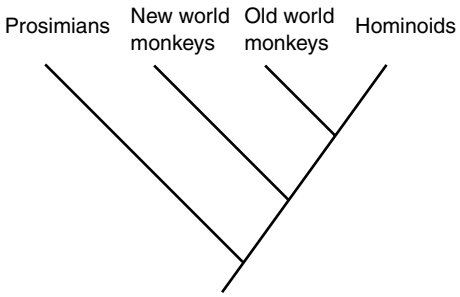

Fig. 1 A phylogenetic tree for the anthropoid primates. The prosimians combine the Lemur species from Madagascar, the nocturnal Lorises from South and Southeast Asia and from Africa, and the Tarsiers from certain islands of Southeast Asia. Generally, prosimians seem to be more ancestral in their morphology compared to the other three groups. The New World monkeys are confined to South and Central America and are, with one exception, the owl monkey, active during the day. They differ from the third group, the Old World monkeys typically in having a flat nose and separate nostrils. Old World monkeys such as rhesus macaques and baboons are found in Africa as well as in certain parts of Asia. The hominoids combine the gibbons (Asia), the orangutans (Asia), the African apes (gorillas, chimpanzees, bonobos), and humans.

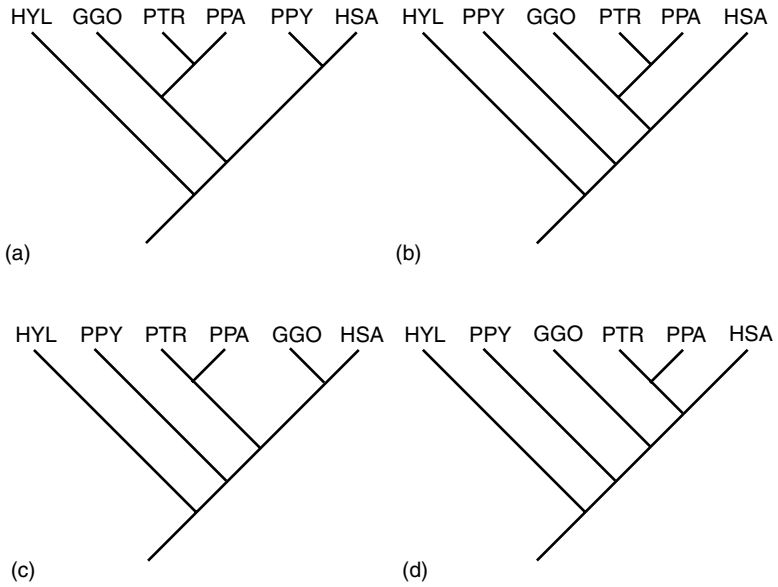

Fig. 2 Alternative phylogenies of the hominoids. HYL: gibbons; PPY: orangutans; GGO: gorillas; PTR: chimpanzees; PPA: bonobos; HSA: humans.

problematic interpretation rendered morphologists unable to conclusively solve the question of hominoid phylogeny.

In the second half of the twentieth century, the expansion of molecular biology provided a new and presumably more powerful approach to phylogenetic studies. The genetic distance between species as reflected in the amount of structural differences between their proteins and nucleic acids was introduced as a more objective measure of their evolutionary relationship. Under the assumption that the accumulation of such differences behaves like a clock

that is synchronized in all species under consideration, those species with a smaller genetic distance are more closely related.

1.1 Phylogenetic Analyses Based on Protein Comparisons

1.1.1 Immunological Comparison of Proteins

The first attempt to resolve primate phylogeny using molecular evidence was based on immunological comparisons of their serum proteins. As the underlying principle, an antiserum against a protein from species X is obtained by immunizing, for example, rabbits or chickens. The degree of similarity between the protein of species X and the corresponding protein in a second species Y is then determined by the extent of cross-reactivity of anti-X-serum and Y-protein. A quantitative measure of similarity is achieved since the antiserum comprises a mixture of antibodies, each recognizing a distinct surface structure (epitope) of the protein used for immunization. The more closely two species are related, the more similar are their proteins and thus, the more epitopes are shared among them. As a consequence, the extent of cross-reactivity increases.

Initial immunological comparisons of primate proteins used antisera against whole blood serum, a rather poorly defined protein mixture. Their results supported the rough classification of anthropoid primates into the major groups already suggested by morphologists (Fig. 1). However, no further resolution was possible since the antigenic properties of hominoid blood sera are too similar to each other to be differentiated by these means.

In later years, increasing understanding of the molecular processes of immune response in combination with the ability to generate antisera against individual proteins facilitated the development of more sensitive immunological assays. On the basis of such improved methods, the African apes and not orangutans were assigned as the closest relatives of humans. But subsequent determination of the branching order of the individual African ape species and humans failed for mainly the following reason. For proteins that differ only slightly, the correlation between the observed immunological difference and the genetic distance is not absolute. As an example, protein A from species X differs from the corresponding protein in species Z in three positions. By chance, none of these differences affect the antigenic properties of the respective proteins; therefore, no difference will be detected in an immunological assay with anti-A_X-serum. Protein A from a third species, Y, however, differs only in a single position from A_X which, again by chance, affects an epitope recognized by the anti-A_X-serum. The resulting lower cross-reactivity with anti-A_X-serum erroneously suggests a higher genetic distance between species Y and X than between species Z and X and thus, a grouping of X and Z to the exclusion of Y. This fuzziness in combination with a substantial experimental effort for the individual assays renders immunological comparisons not suitable to infer the evolutionary relationships of closely related species.

1.1.2 Electrophoretic Comparison of Proteins

Proteins contain amino acids with basic or acidic side chains and thus are charged molecules under most pH-conditions. This circumstance is exploited to separate proteins on a matrix according to their size and their net charge by application of

an electric field. Additional resolution can be achieved by a preceding separation of the proteins according to their isoelectric point – the pH where the net charge is 0 (2D electrophoresis). Variants of a particular protein that differ in their net charge because of sequence differences involving charged amino acids can be identified by their different mobility on the matrix. The application of protein electrophoresis in phylogenetic analyses is based on the fact that the degree of difference in the mobility pattern between related proteins approximately reflects their extent of amino acid sequence difference. Thus, similar to immunological comparisons, protein electrophoresis provides an estimate of the genetic distance between species that forms the basis of phylogenetic conclusions.

The most extensive study to reconstruct the phylogeny of hominoids by means of protein electrophoresis was based on a 2D electrophoresis of 383 fibroblast proteins. Concordant to conclusions from immunological distances of the hominoids, it supports an early separation of the gibbons followed by the lineage leading to orangutans. Notably, the study suggested a smaller genetic distance between humans and chimpanzees than between either species and gorillas. This lends support to the model that humans are the closest relatives to chimpanzees and bonobos (Fig. 2d).

However, similar to the immunological comparison of proteins, electrophoretic analyses can detect only a certain subset of amino acid differences between proteins. Only about 30% of all amino acid substitutions alter the charge and, therefore, the mobility pattern of a protein during electrophoresis. For closely related species, this poses the same resolution problem as already discussed for the immunological comparison of proteins.

1.1.3 Amino Acid Sequence Comparison

The direct comparison of their amino acid sequences represents the most accurate way to assess the degree of difference between two proteins. Even though experimentally elaborative, it provides the opportunity to also trace those changes in the protein sequence that neither affect the immunological properties nor the charge of a protein.

Despite this better resolution, the phylogenetic insights from comparative sequence analyses of hominoid proteins are limited. A data set of 1271 amino acid positions from 9 different polypeptides revealed an average similarity between human and chimpanzee proteins of 99.6%. A similar analysis with a smaller data set comparing humans, chimpanzees, and gorillas determined the average amino acid sequence similarity between humans and gorillas and between chimpanzees and gorillas to be slightly lower (99.3%). Even though this implies a closer relationship between humans and chimpanzees to the exclusion of gorillas, the number of informative positions was far too low to allow decisive conclusions.

Hindered by the disproportionate experimental effort, this data set has never been substantially enlarged. Rather, the focus of evolutionary biologists shifted from the comparison of proteins to the comparison of DNA sequences between species.

1.2 Phylogenetic Analyses Based on DNA Sequence Comparisons

At least two reasons suggest that comparative analyses of DNA sequences are more suitable for reconstructing the phylogeny

of closely related species than the comparison of proteins. First, the molecular clock of DNA sequences ticks faster than that of protein sequences and, therefore, provides a better resolution in time. This is because in coding sequences of genes, three types of positions can be distinguished: nondegenerated sites where any of the three possible nucleotide substitutions is nonsynonymous, that is, it alters the encoded amino acid. Twofold-degenerated sites where only two of the three possible nucleotide substitutions are nonsynonymous. And finally, fourfold-degenerated sites where no nucleotide substitution changes the encoded amino acid. Thus, only a subset of DNA sequence changes translates into changes of the respective protein. Furthermore, a change of the protein sequence generally interferes with protein function and is therefore commonly removed by purifying selection. Therefore, the accumulation of nonsynonymous DNA sequence differences and the consequent accumulation of amino acid sequence differences in proteins is considerably slow. In contrast, nucleotide sequence changes that leave the encoded protein unaltered are less likely subject to purifying selection and thus, accumulate differences at a substantially higher rate. Second, comparative molecular analyses can be extended to those regions in the genome that are not protein-coding, and in the optimal case, not functional at all. The latter sequences should be most informative for phylogenetic analyses of closely related species since they are likely to evolve free of selective constraint.

1.2.1 Comparative DNA–DNA Hybridization

DNA occurs in nature usually as a double helix where the two complementary strands are connected by hydrogen bonds formed between guanine and cytosine, and adenine and thymine respectively. Heating DNA duplexes breaks the hydrogen bonds and the two strands are separated – the DNA is ''denatured'' or ''melted''. The progress of this process can be quantified as it gradually increases the UV absorption at 260 nm of the DNA solution. Upon cooling, complementary DNA strands will rehybridize to duplex DNA. Performing the rehybridization in the presence of DNA from a second species, heteroduplexes can be formed where the two complementary strands stem from different species.

The temperature required to separate 50% of the DNA duplexes, also called the *melting temperature* (T_m), increases, depending on a number of factors: (1) The guanine and cytosine content (GC content) of the DNA: guanine and cytosine pair with three hydrogen bonds whereas adenine and thymine pair only with two hydrogen bonds; (2) the length of the analyzed fragments; (3) the degree of sequence similarity between the two strands forming the duplex. Accordingly, controlling for base composition and duplex length, the difference between the melting temperature of DNA heteroduplexes and that of the corresponding homoduplexes – both strands stem from the same species – (ΔT_m) serves as a measure for the genetic difference between species. For closely related species, the correlation between ΔT_m and the number of mismatches between the complementary strands of a DNA duplex is approximately linear.

An application of this method to the problem of hominoid phylogeny confirmed the conclusions from protein comparisons that gibbons, followed by orangutans, are the most diverged species. Furthermore, additional support was given to the view that humans and chimpanzees

shared a common ancestor after the separation of the gorilla lineage.

However, conclusions based on hybridization experiments have been treated with caution since ΔT_m is likely to be partially determined by factors of uncertain identity. The unclear influence of experimental conditions and of genomic organization such as the presence of duplications, which facilitates hybridization of nonhomologous DNA sequences, were among the main points of critique.

1.2.2 Mitochondrial DNA

In the pre-PCR era, the use of nucleic acids for phylogenetic analyses was substantially complicated by the need to reproducibly isolate the region of interest – usually a fragment of a few hundred base pairs (bp) – from a genome several million to few billion base pairs in size. To minimize this problem, initial focus was laid on the genome of mitochondria, which has a size of only approximately 16 000 bp in humans, and is generally present in more than 1000 copies per cell.

Isolated mitochondrial genomes from the hominoid species have been compared by two different methods. Restriction enzymes – enzymes that cut DNA at specific recognition sites – can be used to test for the presence and relative position of their respective cleavage site in a DNA sequence (the phylogenetic informative character in this approach). On the basis of restriction maps of their mitochondrial genomes, chimpanzees were placed – in contrast to results from other molecular comparisons – closer to gorillas than to humans. However, little statistical support was provided for that conclusion and alternative phylogenies were almost as likely.

Similar to the situation with comparative analyses of proteins, the most accurate way to determine the exact degree of difference between nucleic acids is to directly compare their sequences. Parts, and later, the sequences of the entire mitochondrial genome of hominoids were determined and compared. In these studies, chimpanzees appear again to be closer related to humans than to gorillas.

1.2.3 Nuclear DNA

Meanwhile, modern techniques of molecular biology provide a rapid and reproducible access to the DNA sequence of almost any region in a genome. As a consequence, a variety of data sets have been collected from the nuclear genome that address the question of hominoid phylogeny with particular regard to the relationship of humans, chimpanzees, and gorillas (Table 1). For practical reasons, early studies compared DNA sequences of coding regions from genes. Later, increasing focus was laid on the comparison of noncoding and potentially nonfunctional DNA sequences such as introns, pseudogenes, or intergenic regions. These DNA sequences appear to be the best possible data source for phylogenetic studies on closely related species. However, as can be clearly seen in Table 1, the supported phylogenetic relationship of humans, chimpanzees, and gorillas varies according to the analyzed genomic region.

Apparently, two factors have prevented the hominoid phylogeny from being determined by means of molecular comparisons: first, the insufficient accuracy and resolution of most comparative methods, and second, ambiguous information content in the molecular data itself. In order to determine which of the alternative phylogenies represents the true order in which the lineages to the individual hominoid species emerged (species tree), it is necessary to understand why phylogenetic trees estimated from DNA

Tab. 1 Comparative DNA sequence data sets to resolve the phylogeny of humans, chimpanzees, and gorillas.

Number of genomic loci	*Total compared length [bp]*	*Numbers of loci supporting phylogeny*[a]			
		(H,C)G	*(H,G)C*	*(C,G)H*	*(H,C,G)*
45	46 855	23	8	8	6
53	24 237	31	10	12	0
51	62 530	26	10	12	3

Notes: H: human; C: chimpanzee; G: gorilla.
[a]The grouped species shared a common ancestor after the separation of the third species. (H,C,G) represents those loci that could not resolve the phylogeny (trifurcation).

sequences (gene trees) can differ from the species tree. Mainly two problems need to be considered: first, sampling only a finite number of nucleotides from a locus produces a stochastic sampling error and thus, bears a probability to infer an incorrect gene tree; second, the model where the time point at which corresponding DNA sequences from different species last shared a common ancestor is identical to the time point of speciation is too simplistic. Figure 3 shows an example where the presence of sequence variants of the analyzed locus in the ancestral population in combination with lineage sorting can cause gene tree–species tree incongruities. Especially for species where the amount of genetic polymorphisms in their ancestral population was high and the time between subsequent speciation events was short – both seem to apply to the common ancestor of chimpanzees, humans, and gorillas – lineage sorting renders phylogenetic conclusions based on only a single locus unreliable. Therefore, a joint analysis of multiple independent DNA sequence data sets was required to eventually end the debate concerning the phylogeny of hominoids with sufficient statistical support. Humans are the closest relatives of chimpanzees and based on molecular evidence, both species separated approximately 4.6 to 6.2 million years ago. The likewise estimated date for the speciation of gorillas ranges from 6.2 to 8.4 million years before present.

1.3 Genetic Diversity

DNA sequence evolution is a continual process in time. Therefore, DNA sequence

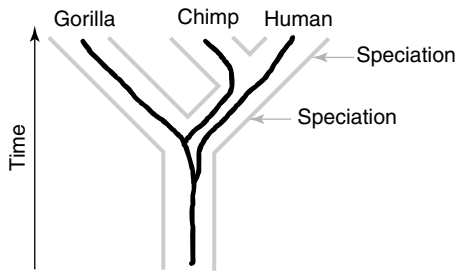

Fig. 3 Gene tree–species tree incongruities due to ancestral polymorphisms and lineage sorting. The gray and black lines represent the species tree (true phylogeny) and the gene tree respectively.

differences exist not only as divergence between species but also as diversity within species. In analogy to the use of divergence to reconstruct a phylogenetic tree that helps infer the evolutionary relationships among species, diversity data can be used to model a within-species tree representing the relationships of sequence variants at a given locus in a population. Such a genealogical tree can help clarify the demographic history of an individual species. Following a genealogical tree backwards in time, the genetic lineages represented by the individual alleles will gradually join until only a single lineage remains. This lineage from which all extant sequence variants are derived is termed the *most recent common ancestor* (MRCA). Making an assumption about the mutation rate and the long-term population size of the species – diversity increases with an increase of either parameter – the estimated time point of the MRCA can be inferred and reflects the amount of diversity present in the extant population.

For chimpanzees and humans, the date of their MRCAs as assessed from single nucleotide polymorphism data is 1 900 000 years and 500 000 years before present respectively. Accordingly, contemporary chimpanzees are two to fourfold more diverse compared to contemporary humans. What can explain the differing amounts of genetic diversity between both species? Since there is clear indication that the mutation rate in chimpanzees and humans is approximately the same, a difference in their population history is proposed as the underlying cause. Contemporary humans are, presumably, descendants of a small African population that subsequently expanded and spread over the entire world. Owing to the small size of the founding population, the majority of DNA sequence variation present in the ancestral human population has been lost, and thus, the genetic diversity in present day humans is low. Chimpanzees, in contrast, are believed to have not undergone such a substantial population size decrease. Therefore, a larger proportion of old genetic lineages could contribute to their present day diversity.

From the analysis of genetic diversity in chimpanzees, a second interesting aspect emerges. According to the location of their habitats in Africa, three groups of chimpanzees are distinguished: western, central, and eastern chimpanzees. From the perspective of DNA sequence variation of the mitochondrial genome and at a Y chromosomal locus, each of the three groups appear to be genetically unique. No shared DNA sequence variants for these loci have been observed, which indicate an independent evolution of the three chimpanzee populations. As a consequence, they were given the status of a subspecies: western chimpanzee (*Pan troglodytes verus*), central chimpanzee (*P. t. troglodytes*) and eastern chimpanzee (*P. t. schweinfurthii*). However, no such genetic uniqueness is seen at autosomal and X chromosomal loci. This was initially taken as an indication that the respective chimpanzee populations do not evolve independently and raised doubts on the biological significance of their classification into different subspecies. Recently, an alternative explanation has been proposed that would be consistent with an independent evolution of the chimpanzee populations. Subsequent to the reproductive isolation of populations, shared ancestral polymorphisms will gradually become extinct by genetic drift, that is, the stochastic loss of alleles caused by the fact that some individuals in a generation

have no offspring whereas others have several. Eventually, no ancestral alleles will be retained and the respective populations are genetically unique. It is now crucial for the case of the chimpanzee populations that the time needed to complete this process depends on the effective population size and thus varies among the analyzed loci. Mitochondrial and Y chromosomal loci will have removed ancestral sequence variants first, since their effective population size is the smallest – only one sequence variant is passed on to the next generation. X chromosomal loci will need on an average triple the time since they have a threefold higher effective population size – two copies in females, and one copy in males. And the time for autosomal loci to become genetically unique is about four times that of mitochondrial and Y chromosomal loci since on an average four copies – two copies each in males and females – are passed on to the next generation. As a consequence, the presence of shared sequence variants at biparentally inherited loci in the three chimpanzee populations in contrast to their genetic uniqueness at mitochondrial and Y chromosomal loci could indicate that the subspecies started to evolve independently – in evolutionary scales – only recently. Therefore, the time was not sufficient to establish genetic uniqueness at all loci.

2 Comparison of the Chimpanzee and Human Genomes

Early comparative studies of their proteins and DNA sequences have already provided evidence that chimpanzees and humans are genetically highly similar. However, differences exist that are informative in two ways. They help understand how genomes diverge subsequent to reproductive isolation of two populations. And they help identify those changes that form the genetic basis of the phenotypic properties differentiating chimpanzees from humans.

Four categories of differences between the genomes of chimpanzees and humans will be discussed in the following text.

2.1 Cytogenetic Differences

The microscopic comparison of chimpanzee and human chromosomes revealed a small number of cytogenetic differences, that is, differences in either chromosome number or differences in presence, order, and position of large chromosomal segments. Their detection was greatly simplified by chromosome banding techniques as well as fluorescence *in situ* hybridization (FISH), methods that allow a specific and reproducible labeling of individual chromosomal regions. The most apparent difference between the genomes of chimpanzees and humans is the number of chromosome pairs per cell. While chimpanzees – as well as gorillas and orangutans – have 24 pairs, humans have only 23. A comparison of the chromosome banding patterns between the species revealed that human chromosome 2 is present as two separate chromosomes (12 and 13) in chimpanzees (Fig. 4a). A subsequent molecular characterization revealed that a fusion at the ends (telomeres) of two ancestral chromosomes gave rise to human chromosome 2.

Seven additional chromosomes, human chromosomes 4, 5, 9, 12, 15, 16, and 17 differ between humans and chimpanzees by an inverted arrangement of chromosomal segments. In all cases, the inversion breakpoints are located on either side

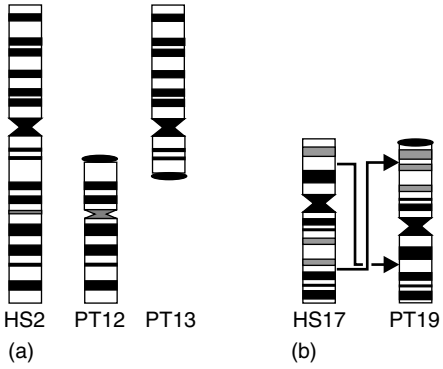

Fig. 4 Examples of cytogenetic differences between humans and chimpanzees. Chromosomes and chromosome bands are not drawn to scale. (a) Human chromosome 2 (HS2) is present as two separate chromosomes in chimpanzees (PT12, PT13). (b) Human chromosome 17 (HS17) and chimpanzee chromosome 19 (PT19) differ by a pericentric inversion. Arrows mark the inversion breakpoints.

of the centromere (pericentric inversion) (Fig. 4(b)). To date, the inversion breakpoints of a single human chromosome, human chromosome 17, have been analyzed on the DNA sequence level, and the breakpoints in three additional chromosomes, human chromosome 4, 9, and 12, have been mapped to intervals of 1 to 2 Mb. So far, no gene was found to be structurally modified by these inversions.

Finally, a number of chromosomes differ between chimpanzees and humans in the amount of constitutive heterochromatin, chromosomal regions that remain condensed throughout the cell cycle and generally do not contain genes.

Cytogenetic differences are discussed to comprise evolutionary important changes that contributed to the initial separation of chimpanzees and humans. Somewhat in contrast to this view, currently no evidence exists that the function of a gene has been affected by any of the observed chromosomal rearrangements. However, pericentric inversions can establish reproductive isolation between populations without the necessity of an altered gene function. In a heterozygous state, an individual carries one normal and one inverted copy of the chromosome, pericentric inversions can substantially interfere with the fertility of the individual. Crossing-over during meiosis in the inverted region generates recombination products that are generally incompatible with life. Thus, it can be speculated that the pericentric inversions differentiating the chromosomes of contemporary chimpanzees and humans comprised early reproductive barriers that facilitated the separation of the two species.

2.2 Subchromosomal Rearrangements and Repeat Content

In contrast to the well-defined extent of cytogenetic differences between humans and chimpanzees, the amount of genomic differences whose size is below the resolution of cytogenetic methods is still unclear. Subtelomeric regions, those genomic segments that are located directly adjacent to the chromosome ends, appear to be dynamic structures that undergo rapid changes over short evolutionary distances. For example, a subtelomeric region formed by a 32-bp repeat unit present at many chromosome ends of chimpanzees and almost all chromosome ends of gorillas is not found in humans. Similarly, a genomic locus that exists only as a single copy in the subtelomeric region of chimpanzee chromosome 17 is found in

eight additional chromosomes in humans. The reason for these rapid changes in the subtelomeric region of chromosomes is still unclear.

From the analysis of the human genome draft sequence, it emerged that about 5% of the DNA sequence – preferentially in the regions around the centromeres – represents evolutionary recent duplications of chromosomal segments with a DNA sequence identity of >90%. Interestingly, initial calculations reveal that more than 7000 exons are transcribed from these duplicated segments. Thus, gene duplications due to segmental duplications provide good candidates for species-specific evolution. Comparing the duplication pattern for human chromosome 22 between humans and chimpanzees, differences are seen, which imply that loss and gain of duplicated elements is an ongoing process in human and chimpanzee evolution. However, comparative analyses focusing on segmental duplications have just started. Therefore, the exact amount of differentially duplicated segments in the chimpanzee and human genomes as well as the number and identity of possibly involved genes remains to be determined.

Around 45% of the human genome consists of repetitive DNA sequences due to the expansion of various groups of mobile elements in the genome. As an example, a particular class of repeats termed *Alu-elements* are present in more than one million copies in the human genome comprising ~10% of the entire DNA sequence. Even though the overall mobility of transposable elements has markedly decreased over the past 35 to 50 million years, transposition is still ongoing in the human and, presumably, also in the chimpanzee genome.

Repetitive elements can propagate genetic differences between species by mainly two ways. First, the insertion of individual transposable elements into regulatory or coding regions of genes can alter expression and function of the affected genes. As an example, humans differ from chimpanzees – and from all other primates – by an inactivation of a gene *CMAH* whose product is essential for the generation of a certain glycoprotein. This inactivation is due to a human-specific insertion of an Alu-element that replaced a 92-bp long exon and, in addition, causes a frameshift in the subsequent coding sequence. The gene modified thus is expressed into a truncated and nonfunctional protein and is responsible for the only proven biochemical difference between chimpanzee and human cells to date. Second, intrachromosomal crossing-over mediated by direct or inverted repetitive elements can cause deletions and inversions, respectively. For example, exon 35 of the human tropoelastin gene has been deleted presumably by a recombination event between two flanking Alu-elements.

In summary, several factors can account for genetic differences between humans and chimpanzees on a subchromosomal scale. However, a determination of the extent to which they each contribute to the total amount of differences between both genomes must await more comprehensive studies.

2.3 Substitutional DNA Sequence Differences

The most frequently detected difference between chimpanzee and human DNA sequences is caused by substitutions of individual nucleotides. Initial studies suggested that per 200 compared nucleotide positions, only about 3 differ between humans and chimpanzees, equivalent to a mean sequence difference of around

1.5%. Many of these estimates were based on the comparison of short stretches of DNA from only one or few regions of the genome. However, different regions in the human genome differ in aspects such as gene content, transcription frequency, base composition, and recombination frequency all of which are suspected to influence the evolutionary rate of DNA sequences. Thus, sampling of DNA sequences from a multitude of loci distributed throughout the genome is required to obtain a relevant estimate of the average amount of substitutional DNA sequence differences between two species. On the basis of genome-wide comparisons of DNA sequences between humans and chimpanzees, their average amount of DNA sequence difference was recently determined to be 1.2%. The results furthermore reveal that indeed genomic regions vary substantially in their divergence among species (Fig. 5).

In absolute numbers, a mean DNA sequence difference of 1.2% corresponds to a total of about 40 million substitutional DNA sequence differences between the human and chimpanzee genomes. However, only a tiny proportion of the human genome – about 3% – is believed to be relevant for gene function. This suggests that less than (only) 1.2 million substitutional differences account for the distinct phenotypes of humans and chimpanzees.

2.4 Insertions and Deletions

Processes that are capable of removing nucleotides from DNA or adding nucleotides to DNA (deletions and insertions respectively) comprise a further source of genetic difference between species. Insertions and deletions mediated by transposable elements or by duplications of chromosomal segments have already been

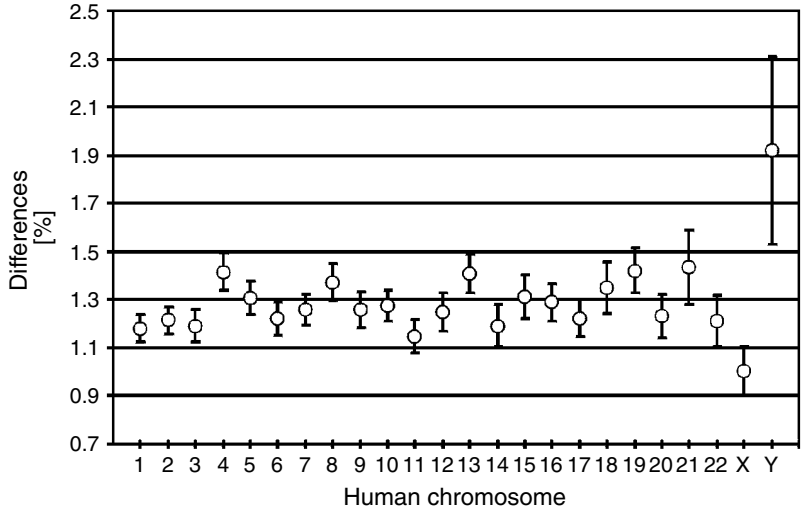

Fig. 5 Mean DNA sequence differences between humans and chimpanzees by human chromosome. Bars indicate 95% confidence intervals. [Reprinted with permission from Ebersberger, I., Metzler, D., Schwarz, C., Paabo, S. (2002) Genomewide comparison of DNA sequences between humans and chimpanzees, *Am. J. Hum. Genet.* **70**, 1490–1497.]

discussed above (Sect. 2.2). Each of these events generally affects a large number of DNA sequence positions; however, they presumably comprise considerably rare occurrences during human and chimpanzee evolution. Insertions and deletions extending only over a few nucleotides apparently occur far more frequently in DNA sequence evolution. A comparison of around only 700 kbp of genomic DNA sequence between humans and chimpanzees has detected already over 1000 individual insertions and deletions. About half of these extend over only 1 to 2 nucleotides and 95% do not exceed 20 bp in length.

Currently, it is estimated that a total of about 4% of DNA sequence in the chimpanzee and human genomes has no counterpart in the respective other species. This indicates that insertions and deletions contribute substantially both in the number of events and in the number of affected positions to the DNA sequence differences between species. Since insertions and deletions also appear to be commonly located in functional regions of the genome, they need to be considered as likely causes for phenotypic differences between humans and chimpanzees.

3 Chimpanzees in Evolutionary Research

Prior to describing the relevance of chimpanzees in evolutionary analyses – I will only focus on biological evolution and omit the complex topic of the evolution of culture – the term *evolution* itself shall be briefly discussed. In the broadest sense, evolution can be regarded as mere change of distinct characters over time. In the more specific view of biologists, evolution represents heritable changes in a population that spread over many generations. The only changes that can be stably inherited comprise modifications in the DNA sequence. Thus, in a strict sense, biological evolution is, ultimately, synonymous to DNA sequence evolution and evolutionary research aims at identifying the factors that determine emergence and accumulation of DNA sequence changes. In reality, however, it is far more practicable to study biological evolution at two levels: molecular evolution comprised of the change of DNA sequences over time, and the evolution of phenotypes leading to the differentiation of individual species. This distinction appears to be indispensable for the following reasons. The genetic basis of the vast majority of observed phenotypic differences between two species is generally, and in the better case, not well understood. Therefore, it is not feasible to study their evolution on the DNA sequence level. Furthermore, the majority of DNA sequence changes, at least in the genomes of mammals, has no effect on the phenotype since approximately 97% of the genome has no obvious function. As a consequence, the evolution of DNA sequences is in major parts independent of the evolution of phenotypes.

However, in order to arrive at a comprehensive understanding of biological evolution, the interdependence of DNA sequence evolution and phenotypic evolution needs to be determined. Here, the analysis of chimpanzees in comparison to humans is likely to provide relevant new insights.

3.1 DNA Sequence Evolution

The advantage of DNA sequence comparisons between chimpanzees and humans to shed light on the factors that determine DNA sequence evolution is twofold.

First, corresponding DNA sequences in the two species differ only in about 1.2% of the positions. This reduces the risk that individual positions have changed more than once in one species, or parallel in both species since the sequences last shared a common ancestor. Such multiple or parallel substitutions blur the correlation between the true and observed number of changes and comprise a substantial problem in the evolutionary analysis of DNA sequences. Second, the close relationship between chimpanzees and humans justifies the hope that factors determining rate and mode of DNA sequence change do not differ substantially between the two species. The approach to analyze DNA sequence evolution by a DNA sequence comparison between chimpanzees and humans is straightforward. Different regions in the human genome vary in divergence to the chimpanzee. Any genomic feature that is found to covary with the divergence can serve as a candidate to influence DNA sequence evolution. However, in order to correctly interpret the data, one pitfall needs to be regarded that has been already mentioned in Sect. 1.3. Genomic regions can differ in their divergence between humans and chimpanzees even though they evolve at the same rate. This problem arises since the time point at which the human and chimpanzee DNA sequences last shared a common ancestor is not the same throughout the genome. It is required to take this into account in order to identify regions that truly differ in their evolutionary rate.

When DNA sequences from different regions of the chimpanzee genome are compared to the corresponding sequences in humans, it is seen that different chromosomes vary in the amount of DNA sequence differences between humans and chimpanzees (Fig. 5). Interestingly, the extent of divergence for the individual chromosomes is correlated with the evolutionary time they spend in the male germ line. The X chromosome, which spends the least time in the male germ line, displays also the least divergence (1.0%), the Y chromosome, which is confined to the male germ line, displays the highest divergence (1.9%), and the divergence of the autosomes, which spend an intermediate time in the male germ line ranges between that of the sex chromosomes (1.2%). Currently, it is assumed that a mutation rate about threefold higher in the male germ line compared to the female germ line is responsible for this observation. However, it is noteworthy that the evolutionary rates also differ among autosomes that spend the same amount of time in the male and female germ line respectively. This indicates the existence of further factors that influence the accumulation of DNA sequence differences in the human genome. Recently, a second genomic feature has been found to covary with DNA sequence divergence between humans and chimpanzees. Regions with a high recombination rate also display a high divergence between the two species, while regions with a lower recombination rate have diverged less. This can be taken as an indication that the process of recombination is mutagenic and thus, drives DNA sequence evolution.

The amount of comparative DNA sequence data between chimpanzees is still limited. However, more extensive studies are likely to give further insights into how different factors interact to shape the rate and pattern of DNA sequence evolution in the genomes of humans and chimpanzees.

3.2 From Genotype to Phenotype

Maybe the most widely noticed field in evolutionary research is concerned with the emergence of new phenotypes that contribute to the uniqueness of individual species. Mainly three aspects are in the focus of interest: (1) When did the new phenotype arise? (2) Was it chance or selective advantage that caused its fixation in the species? (3) What are the genetic changes that underly the particular phenotype? While the answers to the first two questions are mainly of academic interest, the correlation between genotype and phenotype is – as will be discussed in Sect. 3.3 – of immediate practical use.

When comparing humans and chimpanzees, the impression is that both species are strikingly alike, yet show a certain set of well-defined differences. Meanwhile, an extensive catalog of phenotypic differences between humans and chimpanzees has been collected. Among the most well-known examples are bipedal walking, enlarged brain size, and spoken language, which distinguish humans from chimpanzees and all other primates. This set of phenotypic differences is opposed by a considerably low amount of genetic differences (see Sect. 2), which provides an excellent starting point for the correlation of genotype and phenotype. Two approaches can be chosen for such a venture. In a bottom-to-top strategy, the genomes of humans and chimpanzees are screened for differences that affect gene function. This can be either changes in the coding region of genes resulting in a structural change of the gene product, or in regions that control the expression pattern of a gene. While the identification of differences potentially affecting gene function is considerably simple, the subsequent determination of the likely effect on the phenotype is experimentally extremely demanding. In the first step, the function of the affected gene must be determined, and in the next step, the influence of the genetic change on the respective function of the gene product must be determined. This latter step will be especially problematic for such changes that affect the expression pattern of genes rather than the structure of the gene product. Eventually, inferences of the likely phenotypic consequence of the genetic change can be made. The reverse approach, a top-to-bottom strategy, starts from a recognized phenotypic difference between humans and chimpanzees. Certain genes that are known or suspected to contribute to the phenotype of interest are assigned as candidates whose DNA sequence can be screened for differences between humans and chimpanzees. Once species-specific differences are found for a candidate gene, the subsequent procedure resembles that of the bottom-to-top strategy with the subtle but essential difference that a particular phenotype has been already correlated with the gene.

To date, the study of candidate genes has been successfully applied at least in two studies, one of which originated from the observation of a structural difference between the cell surfaces of humans and great apes. It could be shown that this is due to an inactivation of an enzyme on the human lineage caused by a deletion in the corresponding gene (see Sect. 2.4). Even though this comprises a marked biochemical difference between human and chimpanzee cells with possible implications for the intercellular cross talk, the relevance of this difference for human evolution is still unclear. A second study focused on a gene *FOXP2*, which when mutated, causes a distinct type of speech impairment in humans.

A comparison of this gene between humans, chimpanzees, and other primates revealed that it carries two human-specific nucleotide substitutions, each of which translates into an amino acid substitution in the encoded protein. This becomes especially interesting in the light that this protein is evolutionarily highly conserved. Between humans and mice, only three amino acid changes are observed; two of which occur on the human lineage. Furthermore, there is indication that this gene has been the target of selection during recent human evolution. Both observations in combination can be judged as an indication that the respective gene could have a certain relevance for the evolution of spoken language in humans.

These examples demonstrate that, indeed, the comparison of humans and chimpanzees is capable of detecting genetic changes that can be correlated with phenotypic differences between both changes. This justifies the hope that in a step-by-step process, even the genetic frameworks of traits as complex as (spoken) language can be identified.

3.3 Comparative Analysis of Gene Expression

The phenotypic appearance of a species is not only dependent on the functional integrity of its genes but also on their correct activation with respect to time, place, and extent. Genetic changes that alter this construction plan of a species provide a powerful tool to achieve substantial phenotypic changes over a very short time period. In view of the low genetic difference between humans and chimpanzees, it was considered in early comparative studies that changes in a few ''master genes'' – genes that control gene expression at certain key points of development – account for the phenotypic differences between both species.

To date, such master changes, if they exist, remain to be identified. However, as a first step, evidence was provided that the pattern of gene expression indeed varies in a species-specific way. When the expression pattern of nearly 18 000 genes is analyzed for several human and chimpanzee individuals, it is found to be more similar among individuals of the same species than between species (Fig. 6). Starting from this observation, follow-up studies have to determine whether the evolution of gene expression is mainly due to regulatory changes in individual genes or whether a cluster of functionally related genes changes their expression in a concerted manner due to a switch in a shared master gene. Furthermore, those individual genes that have substantially changed

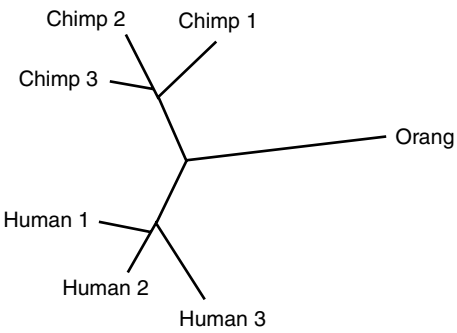

Fig. 6 Relative extent of the differences in the expression pattern within and between species. The expression pattern jointly determined from nearly 18 000 genes is found to be more similar within humans and chimpanzees respectively, than between both species.

their expression pattern in humans or chimpanzees comprise candidates for phenotypic differences between both species and thus, should be the subject of comparative studies as described in the previous section (Sect. 3.2).

4
Chimpanzees in Biomedical Research

The cure or prevention of diseases is one of the major interests in human research. In the study of disease-causing processes on the cellular and molecular level, nonhuman primates in general, and chimpanzees in particular, can be regarded as important model organisms. Their similarity to humans renders them susceptible to a number of pathogens correlated with human diseases. Thus, the infection of primates under controlled laboratory conditions allows the study of the onset and progress of the respective disease with a resolution far beyond what can be achieved by observatory studies in humans. Furthermore, as a result of the growing understanding of disease-causing processes, new therapeutical strategies and medicines will be developed that specifically target individual pathways in the human metabolism. Therefore, the traditional model organisms that are rather distantly related to humans may no longer be suitable to test the efficacy and safety of these medicines. Rather, model organisms such as the chimpanzee are required that resemble the human metabolism as closely as possible. Eventually, certain human diseases and pathogens appear to affect chimpanzees either to a lesser extent than humans, or not at all. The identification of the underlying molecular basis of this reduced susceptibility will provide starting points for new therapeutical approaches to cure the respective disease.

4.1
Are Chimpanzees Good Model Organisms?

The arguments listed above comprise a clear vote for a wide use of chimpanzees in biomedical research. Accordingly, numerous research facilities founded chimpanzee colonies, and in the 1980s, breeding programs were started to insure that enough chimpanzees were available for research needs. However, it appears that the similarity between chimpanzees and a (hypothetical) good model organism for biomedical research is very limited. Such an organism would be rather mouse-sized than chimp-sized. Not only is that desirable due to the limitation of laboratory space and budget for food, it also greatly facilitates handling of the animals during the experiments. Who ever has seen somebody pulling chimps by their tail out of the cage? And this is not because their tails are pretty much nonexisting! Furthermore, a good model organism would have a generation time and a life span substantially shorter than that of chimpanzees. The benefits would be twofold. First, it increases the value of the model organism for research on transgenic animals. The specific inactivation of genes in an organism (knockout) as well as their overexpression or exchange with functional homologs from other species (knockin) gains increasing importance in the study of function and evolution of genes and gene products. A minimal time span between the genetic modification of the individual – this generally happens at a very early stage in development – and the latest possible observation of the corresponding phenotypic effect is desirable for both kinds of studies. The latter time point is obviously

determined by the life span of the model organism. Furthermore, once an individual carrying the desired genetic modification has been generated – which is still a costly, time-consuming, and experimentally elaborative venture – its maintenance as a laboratory strain is generally desirable. This, however, is only feasible when the generation time of the respective species is in a reasonable range of at most a year. A slowly developing, late reproducing, and long living species such as chimpanzees is thus, not particularly well suited for standard research on transgenic animals. Second, an early (natural) death of the research animal elegantly solves the problem of what to do with the animals once the experiments are over. Chimpanzees, however, have an average life span of around 40 to 50 years, which is well beyond the duration of most experimental studies. The relevance of this problem becomes immediately obvious when one imagines a group of chimpanzees infected with a human pathogen that need to be taken care of once they are no longer useful for experimental studies.

Clearly, strong arguments exist to use chimpanzees as experimental animals in biomedical research. However, the practical disadvantages are apparent. Together with a number of ethical concerns that I will discuss below (Sect. 4.4), the use of chimpanzees as a standard experimental model organism is clearly voted against. Meanwhile, this has been widely recognized and the number of chimpanzees held as laboratory animals has substantially decreased over the past years. In the case of Europe, invasive experimental studies on chimpanzees have entirely ended.

4.2 Biomedical Differences Between Humans and Chimpanzees

Practical experience has shown that chimpanzees are not suitable as experimental model organisms for studying human diseases, or for testing the efficacy and safety of new pharmaceuticals. Nevertheless, a certain relevance remains for chimpanzees in biomedical research. From long-term observations in primate centers and zoos, differences in susceptibility and severity of certain human diseases between humans and chimpanzees have emerged. A few examples are listed in Table 2. Although the evidence is in parts fragmentary and vague – in certain cases it

Tab. 2 Differences in the disease spectra between humans and chimpanzees.

Medical condition	*Humans*	*Chimpanzees*	*Evidence*
HIV progression to AIDS	Common	Very rare	Definite
Late complication in hepatitis B/C	Frequent	Uncommon	Definite
Malaria[a]	Susceptible	Resistant	Definite
Menopause	Universal	Rare	Definite
Influenza A symptomatology	Moderate to severe	Mild	Likely
Alzheimer's disease pathology	Common	Rare	Likely
Myocardial infarction	Common	Uncommon	Likely
Epithelian cancers	Common	Rare	Likely

[a]Caused by *Plasmodium falciparum* infection.

has mere anecdotal character – the medical relevance of involved diseases such as AIDS, hepatitis, or certain types of cancer is sufficient to draw attention to this issue. Differences in the disease spectrum between two species can be attributed to two different causes: differences in environmental influences such as diet and differing genetic predispositions. In recent years, the environmental conditions for captive chimpanzees have become increasingly similar to those of humans. This, however, had no substantial effect on the differences of their respective disease spectra. Therefore, the existence of crucial genetic differences between the two species must be assumed whose identification comprises the main relevance of biomedical studies on chimpanzees. Conveniently, the identification of candidates for these genetic differences can be achieved by a comparison of the genome sequences of chimpanzees and humans and does not require experimental studies on chimpanzees.

As an outlook, the medical consequences of biomedical studies on chimpanzees are likely to be revolutionary. Once the genetic basis is understood as to why this species is less susceptible to certain human diseases, cure or even prevention of these diseases can be imagined by mimicking the chimpanzee phenotype in well-defined disease-relevant parts of human biology.

4.3 Chimpanzees and Infectious Diseases

Maybe the most widely recognized biomedical difference between chimpanzees and humans is their different susceptibility to AIDS upon infection with HIV-1 (Human Immunodeficiency Virus 1), the most common cause of AIDS in humans. While chimpanzees rarely display AIDS-like syndromes, the progression to AIDS in humans is common. This difference is generally explained by the evolutionary history of HIV-1. It is suggested that HIV-1 originated from the chimpanzee virus SIV (Simian Immunodeficiency Virus) that crossed the species border only about 50 years ago. Thus, the low susceptibility to AIDS in chimpanzees could be due to a long coevolution of virus and host in a way that contemporary chimpanzees get infected by the virus but due to an efficient control of the virus load do not develop the disease. Humans, in contrast, who have become exposed to the virus only recently, lack the immunological ability for virus control and thus, suffer from AIDS. Obviously, the missing development of the disease renders chimpanzees inadequate as a model to study the progress of AIDS. Other primate species, such as the rhesus macaque appear to be more suitable since AIDS-like symptoms have been observed in these species subsequent to infection with SIV. However, the genetic reasons for the adapted immune response that cause the relative resistance against AIDS in chimpanzees are of considerable interest. They might point toward novel therapeutic approaches to prevent the progression to AIDS in HIV-infected humans. Initial insights suggest that differences in the allele combination in the major histocompatibility complex – a collection of genes correlated with immune response – between humans and chimpanzees is responsible for their varying susceptibility to AIDS.

Similar to the case of infection with HIV-1 and progression to AIDS, chimpanzees reduce the risk of long-term complications of hepatitis infections by an effective control of the virus load in the organism. Thus, there appears to be a general capability in

chimpanzees to deal more effectively with virus infections than humans. It will be the main task of future studies to determine the exact elements of the virus–host relationship in chimpanzees that account for this better virus control.

In conclusion, although chimpanzees are not suited as experimental model organisms, there appears to be sufficient reason for the comparison of humans and chimpanzees to become a major field in biomedical research. However, one should be aware that the insights from past biomedical studies in chimpanzees have not met the high initial expectations. The risk remains that the biomedical relevance of genetic differences between humans and chimpanzees is too difficult to interpret just by observatory studies. As a consequence, a substantially increased experimental effort might be required whose realization ultimately depends on the establishment of new experimental systems that replace chimpanzees as a model organism. Such systems should combine a maximum of the advantages provided by chimpanzees as a model organism with a minimum of its practical and ethical concerns.

4.4 Ethical Considerations

Chimpanzees, like all other great apes, are an endangered species that, due to human interaction, face the extinction of their wild populations. From this perspective, it seems somewhat odd to discuss their use for experimental research beneficial primarily to humans. However, chimpanzees breed well in captivity, which insures that enough animals are available for research without affecting the wild populations. In addition, it can be argued that every study, even those with fatal outcome for the participating individual, eventually benefits chimpanzees as a species. For example, vaccines and drugs to cure human diseases developed on the basis of experimental research on chimpanzees will be effective also in chimpanzees. A scenario can be imagined where these pharmaceuticals help save a wild chimpanzee population whose survival is endangered by such a disease. In combination, both arguments would, presumably, be sufficient for a well-controlled use of almost any other species – even one that faces its extinction – as an experimental animal. However, the situation is more complex for chimpanzees. An increasing number of comparative studies reveal that there is no clear-cut qualitative difference distinguishing humans from chimpanzees in a number of areas that have initially been regarded as ''specific to humans.'' Many points of similarities exist in cognition and psychology between chimpanzees and humans. For example, it was repeatedly suggested that chimpanzees can understand and use rudimentary forms of language – even though they cannot speak due to anatomical limitations – and there is certainly tool usage in chimpanzees. In addition, only recently, it was appreciated that chimpanzees have cultural traditions similar to humans. Given these insights and given the high genetic similarity between humans and chimpanzees, it might be worthwhile to reconsider the clear-cut distinction in ''human being'' and ''animal''. The resulting implications for the use of chimpanzees in research are obvious and well recognized. In brief, only such studies should be done with chimpanzees that would be done with humans who are considered not to be able to provide informed consent. As a legal consequence, the government of New Zealand has extended three basic human rights

to chimpanzees: (1) the right not to be deprived of life; (2) the right not to be subjected to torture and cruel treatment; and (3) the right not to be subjected to medical or scientific research that is not in the best interest of this individual.

Whether these ventures and agreements are sufficient to protect chimpanzees from abuse in human research will be seen in the future. As soon as comparative studies of humans and chimpanzees lead to fundamental questions that can be solved neither by DNA sequence comparisons nor by transgenic experiments in model systems, research proposals will arise that include the generation of transgenic – that will be ultimately ''humanized'' – chimpanzees. Therefore, it is an ethical imperative to accompany an extensive comparative study on the chimpanzee genome with a program that studies ethical, legal, and social implications of such research.

5 The Chimpanzee Genome Project

Even under careful consideration of all practical and ethical limitations that are correlated with comparative studies between chimpanzees and humans, the insights based on the availability of a chimpanzee genome sequence are likely to be substantial. As a consequence, the US National Human Genome Research Institute (NHGRI) has recently assigned chimpanzees the top priority for whole-genome sequencing, a decision that might be a pioneer for future research on nonhuman primates. The choice of sequencing the genome of chimpanzees rather than that of the rhesus macaque – the most widely used primate in biomedical research – seems to put more weight on the evolutionary aspect of a human–nonhuman primate comparison than on its immediate value for experimental biomedical studies.

5.1 The Quest for Differences

With respect to the list of eukaryotes whose genome has been entirely sequenced, the choice of determining the genome sequence of chimpanzees comprises the first step into the next phase of comparative genomics. Comparing the genome sequences from yeast, worm, fly, mouse, and human led to the identification of shared, and thus, evolutionarily conserved elements. Follow-up studies mainly aimed at determining the function of these conserved elements and generating a rough view on the genetic framework underlying organismal organization. However, adding chimpanzees to that list shifts the focus ultimately from conserved genomic elements toward the differences between two genomes. As a consequence, the initial outcome of a genome comparison between humans and chimpanzees will be a comprehensive map of their DNA sequence differences. As a second step, the functional consequences of these differences need to be analyzed and, eventually, a fine-scale view on the functional organization of the human genome will emerge.

5.2 Sequencing Strategy and Requirements

Sequencing an entire genome with more than three billion bases is still an enterprise that requires careful planning and strategical considerations. Recent sequencing efforts, including the genomes of *Drosophila*, human, and mouse clearly demonstrated that the whole-genome shotgun sequencing strategy is the fastest and

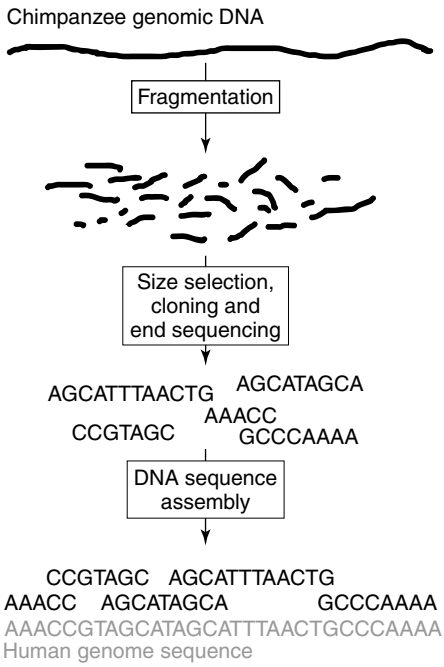

Fig. 7 Whole-genome shotgun strategy to sequence the chimpanzee genome. The entire genome of an individual is fragmented at random positions and genomic libraries with a defined insert size are generated. Subsequently, random clones are picked from the genomic libraries and the DNA sequences of their insert ends are determined. In the assembly step, the individual DNA sequences are aligned to reconstruct a contiguous consensus sequence that represents the original genomic sequence of the chimpanzee. This step is greatly facilitated for the chimpanzee genome since the human genome sequence can serve as a guideline for the assembly.

most efficient way to determine an initial draft sequence of a genome. The general principle of this strategy is outlined in Fig. 7. While the generation of the shotgun sequence reads is considerably straightforward, their assembly to a comprehensive consensus sequence comprises the crucial and most problematic step. This step, however, will be greatly facilitated for the chimpanzee genome. Given the high similarity between both genomes, it will be in most cases straightforward to align the chimpanzee DNA sequence fragments to the human genome sequence. However, special care must be given to those genomic regions that differ between the two species. Human regions not present in chimpanzees will cause gaps in the alignment, while chimpanzee DNA sequences not present in humans will fail to align against the human genome. In addition, recent duplications as well as inversions of genomic regions comprise further obstacles on the way toward a comprehensive draft version of the chimpanzee genome.

Following the shotgun phase of a genome project, remaining gaps and uncertainties in the draft sequence must be removed in the so-called finishing phase. This sequence-finishing is tedious, time-consuming and thus, expensive. However, it is assumed that the majority of comparative studies between chimpanzees and humans will not substantially benefit from a finished, rather than a draft version of the chimpanzee genome. Thus, it is currently considered to initially leave the chimpanzee genome sequence in a draft status. It is estimated that such a draft sequence will cover more than 90% of the chimpanzee genome.

In conclusion, a first draft of the chimpanzee genome sequence can be generated with considerably low effort and is likely to be available by the end of 2003.

However, there is one important issue when working with this draft sequence that played only a very minor role in previous comparative studies of genome sequences. Errors in the draft sequence of the chimpanzee genome, but also in the human genome sequence due to errors in the assembly process or due to sequencing errors suddenly gain relevance. An attempt to identify conserved regions between distantly related species is conservative with respect to the quality of the draft sequence. Regions that have been found conserved between species using early versions of the draft sequence have a high probability of remaining conserved after sequencing errors in the draft sequence have been corrected. It is self-evident that the situation is certainly more difficult when the focus lays on DNA sequence differences between genomes as in the case of the human–chimpanzee comparison. To minimize this problem, every DNA sequence position in the draft version of the chimpanzee genome should get assigned a confidence value to allow a quick assessment of its reliability.

5.3 Human, Chimpanzee, and. . . Future Perspectives

With the availability of the chimpanzee genome draft sequence, the first step into the next stage of comparative genomics will be completed. A comprehensive catalog of genetic differences between humans and chimpanzees will emerge that ultimately reveals those changes responsible for the distinct phenotypic traits of both species. The identification of those presumably few functional changes and the dating of their presumed occurrence will be the main task of future studies. To accomplish this goal, it will be necessary to exactly determine the extent and pattern of genetic variation both within humans and within chimpanzees. This not only helps in identifying those genuine genetic differences between both species that cannot be attributed to polymorphisms in either species but also helps pinpoint those regions in the genomes of chimpanzees and humans for which fewer than average sequence variants exist. Such a reduction of diversity can comprise signatures of selection during recent human and chimpanzee evolution and provide hints for the likely importance of changes that are close by in functional regions of the genome.

Eventually, the detection of genuine genetic differences between humans and chimpanzees can only then be interpreted in a meaningful way when the lineage on which the corresponding change occurred has been determined. Therefore, the genome of a third, more distantly related species is required as an outgroup that helps infer whether an observed DNA sequence difference between humans and chimpanzees is due to a change on the human or the chimpanzee lineage. Presumably, a second anthropoid primate would be optimal as such an outgroup. In order to make full use of the genomic comparison of humans and chimpanzees, the genome sequence of the outgroup species should be determined immediately following the completion of the chimpanzee genome sequence. Likely candidate species are two Old World monkeys regularly used in biomedical research: the rhesus macaque (*Macaca mulatta*), and the baboon (*Papio hamadryas*), or the orangutan (*P. pygmaeus*). Which of these species to choose depends largely on future plans to use primates as experimental animals.

Keywords

Chiral
Describing an object or a molecule whose image in a plane mirror cannot be superposed on the original.

Chiral Drug
A pharmaceutical agent that exists in two enantiomeric forms. In many cases, the two forms will have different physiological activity.

Chiral Methyl
A methyl group with the three hydrogen isotopes, ^{1}H, ^{2}H, ^{3}H. When combined with another group, R, a chiral molecule is obtained: R-C^{1}H^{2}H^{3}H.

Chiral Phosphorous Atom
A phosphorous atom linked to the three oxygen isotopes, ^{16}O, ^{17}O, ^{18}O, and to another group, usually OR: hence, RO–P–^{16}O^{17}O^{18}O.

Chiral Recognition
Discrimination between enantiomers achieved by enzymes or biological receptor molecules and by some chemical catalysts and reagents.

Configuration
Three-dimensional arrangement of atoms or groups of atoms at an element of chirality; arrangements resulting from rotation about single bonds are excluded.

Diastereoisomer
Stereoisomers not in an object-/mirror-image relationship.

D/L Notation
An arbitrary convention to denote configuration about a chiral element in α-amino acids, some α-hydroxy acids, and carbohydrates.

Enantiomer
Stereoisomers that are in an object-/mirror-image relationship.

Homochiral
A molecule or assembly of molecules in which the components have like chirality sense. Normal protein amino acids have L-configuration; for naturally occurring carbohydrates, the D-configuration predominates. The antonym is heterochiral.

Isomer
Compounds having the same molecular formula but differing in the nature or sequence of bonding of their atoms, or in the spatial arrangement of their atoms.

Optical Activity
The property, possessed by some substances (or solutions of some substances) of rotating the plane of plane-polarized light. For a chiral substance, one enantiomer will produce dextrorotation, (+), and the other, levorotation (−).

Prochiral (Prostereoisomerism)
Describing a molecule that yields a chiral structure by replacement of one of two chemically like groups by a different group. Thus prochiral Caabc yields chiral Cabcd by replacement of one ''a'' by ''d''.

Racemic
A mixture of equal amounts of two enantiomers of a compound; this mixture is without optical activity. Hence, racemization, the conversion of an enantiomer to a racemic mixture, is characterized by the time-dependent loss of optical activity.

R/S Notation
An unambiguous method to specify configuration of chiral compounds on the basis of the ordering of atoms or groups of atoms (by a sequence rule) when the molecular model is viewed from a defined direction.

Stereoisomer
Isomers differing only in the spatial arrangement of their atoms.

An object, structure, or molecule for which the image in a plane mirror cannot be superposed on the original is chiral; for example, the two human hands. Chiral structures or growth forms are common in nature and in manufactured objects. A typical chiral molecule contains a carbon atom linked to four different groups, Cabcd. Such molecules exist in two forms of opposite handedness that are termed *enantiomers*. Most metabolites are chiral, and enzymes usually exhibit a high degree of specificity toward enantiomers. A molecule containing two chemically like ''a'' groups, Caabc, is described as prochiral; replacement of one ''a'' group by ''d'' leads to a chiral molecule, Cabcd. Enzymes usually discriminate between the two chemically like groups in a prochiral molecule. Enantiomers can have very different physiological actions, for example, taste or odor. With chiral pharmaceutical agents, the enantiomers may also have different physiological actions. Physiological differences arise from the phenomenon of chiral recognition – the ability of biological receptors, enzymes, and some catalysts and reagents to discriminate between the enantiomers of a given compound. Although many hypotheses account for the homochirality observed on planet Earth, the original process or processes leading to this situation remain unclear.

1 Chirality – An Introduction

The earliest people must have recognized that one human hand, although very similar, cannot be superposed on the other hand and that the reflected image (e.g. on a water surface or in a mirror) of one hand was superposable on the other. In modern terminology, the two human hands are in a mirror-image relationship. The "handedness" of biological structures, molecules, objects, and so on, generates much interest. For understanding, it is necessary to define right and left. Although children are taught to distinguish hands, feet, eyes, ears, and so on, as right or left, a precise definition of right or left in terms of direction is difficult if not impossible. The normal definition is a statistical one – the right hand is the stronger, or that which is used preferentially by the majority. Most of the world's population favors the right hand, and populations with the majority preferentially using the left hand are not known.

A comprehensive terminology describing handedness is based on the words chiral (adjective) and chirality (noun) introduced by Lord Kelvin in 1894 as follows: "I call any geometric figure, or group of points *chiral* and say that it has *chirality*, if its image in a plane mirror, ideally realized, cannot be brought to coincide with itself." Beginning in about 1958, they began to be very widely used. Although based on the Greek word "$\chi\varepsilon\iota\rho$" for hand, the definition of chirality requires only the observation of a mirror image without requiring knowledge of right or left. The two human hands are chiral regardless of their names.

While chirality usually involves three-dimensional structures, it is possible in two dimensions. Thus, the mirror image of the letter F cannot be superposed on the original by translation or rotation in the plane; F is chiral in two dimensions. The letter E is achiral; mirror image and original are superposable.

Chirality, a very pervasive phenomenon in biology, operates at two levels. The first is that of easily observed structures such as the hands. The second concerns atoms and molecules. Since the macrobiological structures depend on enzyme reactions for their formation, the chirality of metabolites, both large and small, determines the chirality of the larger structures. Hence, a brief review of general stereochemical principles will be given before discussing the biological implications. In this article, all of the common amino acids will in some cases be described by the conventional three-letter abbreviations.

2 Molecular Chirality in Biology

2.1 Chirality Descriptors: the *R*/*S* Notation

Isomers are compounds having the same molecular formula but differing in the nature or sequence of bonding of their atoms, or in the spatial arrangement of their atoms. Those isomers differing in their spatial atomic arrangements are called *stereoisomers*. Stereoisomers showing a mirror-image relationship are termed *enantiomers*, whereas stereoisomers not in a mirror-image relationship are *diastereoisomers*. Enantiomers show the same general chemical properties but differ in their interaction with polarized light. One enantiomer will produce a right-handed dextro (+) rotation, the other a left-handed levo (−) rotation. Enantiomers frequently exhibit different properties in biological systems.

Diastereoisomers differ in their general chemical properties.

The major biological concern is with the chirality of carbon compounds. The simplest organic chiral compound is formed by a carbon atom linked to four different noncarbon atoms as in CHBrClF. The spatial arrangements in such a compound are termed *configurations*, and if the precise arrangement is known, it is described as an absolute configuration (arrangements resulting from rotation about single bonds are excluded). Absolute configurations are specified unambiguously by the Cahn–Ingold–Prelog system. The four different atoms or groups of atoms attached to the carbon atom are first arranged in a carefully described priority sequence. The ''sequence rules'' are based on parameters such as atomic number and atomic mass. To be unambiguous, they are complex but are readily available in texts of organic chemistry or stereochemistry. For many groups of biological interest, the following sequence will be adequate; a > b indicates that a has a higher priority than b:

$$\begin{aligned} &\mathrm{Br} > \mathrm{Cl} > \mathrm{SH} > \mathrm{F} > \mathrm{OCH_3} > \mathrm{OH} \\ &> \mathrm{NHCOCH_3} > \mathrm{NH_2} > \mathrm{COOR} > \mathrm{COOH} \\ &> \mathrm{CHO} > \mathrm{CH_2OH} > \mathrm{C_6H_5} > \mathrm{C_2H_5} \\ &> \mathrm{CH_3} > {}^{3}\mathrm{H} > {}^{2}\mathrm{H} > {}^{1}\mathrm{H} \end{aligned}$$

A model of the molecule is then viewed with the atom or group of lowest priority pointing away from the observer. If the remaining atoms or groups of atoms, when examined in order of decreasing priority, show a clockwise or right-handed arrangement, the absolute configuration is denoted as *R* (rectus). A counterclockwise, left-handed path yields the *S* (sinister) absolute configuration. For CHBrClF, the priority is Br > Cl > F > H, and the two possible enantiomeric models are shown in Fig. 1(a, b). The (*R*) enantiomer (Fig. 1a)

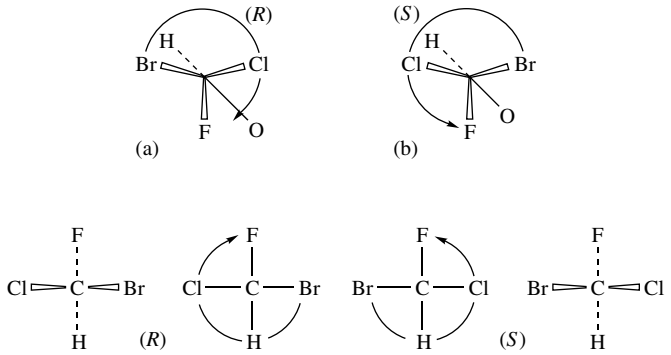

Fig. 1 Enantiomers of CHBrClF. In this and subsequent figures a ''dashed'' line indicates a bond below the paper plane and a ''wedge'' shape indicates a bond above the paper plane. Structures (a) and (b) show the molecular models viewed to determine (*R*) or (*S*) configuration; O = eye of observer. Note that the sequence, Br → Cl → F, describes a right-handed path in (a) and a left-handed path in (b). The bottom drawings determine configuration using projection drawings with the group of lowest priority, H, at the bottom. For each enantiomer, there is a three-dimensional representation and a conventional projection formula.

is levorotatory and, conversely, the (*S*) enantiomer (Fig. 1b) is dextrorotatory.

Three-dimensional molecular arrangements are often represented as two-dimensional ''projection'' drawings by carefully following conventions established by Emil Fischer. In a projection formula, a vertical line indicates a bond pointing below the plane of the paper, while a horizontal line indicates a bond pointing above the plane of the paper; see CHBrClF enantiomers (Fig. 1). If the group of lowest priority is at the bottom of a projection formula, the configuration can be determined from the handedness of the remaining three groups (Fig. 1).

For chirality specification, any projection formula can be transformed so that the group of lowest priority is at the bottom; hence the handedness can be ascertained as just described. This transformation must involve two interchanges of any two groups; such a process retains the original configuration (a single interchange of any two groups inverts the original configuration). For example, (+)-glyceraldehyde is conventionally written with the most oxidized group located at the top (Fig. 2a). The priority sequence is OH > CHO > CH_2OH > H. If the groups H and CH_2OH are interchanged so that the lowest priority H is at the bottom, a structure with inverted configuration is obtained (Fig. 2b). A second interchange of CHO and OH restores the original configuration (Fig. 2c). ''Reading'' the handedness of the sequence, OH > CHO > CH_2OH, gives the configuration of (+)-glyceraldehyde as (*R*).

2.2 Chirality Descriptors: the D/L Notation

Certain groups of metabolites having structures with identical handedness – α-amino acids, α-hydroxy acids, and carbohydrates – are often described by the D/L notation. A projection formula is drawn with the most oxidized group (usually CHO or COOH) placed at the top. The next carbon atom in the vertical chain has invariant groups, H and NH_2 for amino acids, and H and OH for hydroxy acids. Two configurational ''standards'', glyceraldehyde and serine, are used (Fig. 3). If in such formulae, the NH_2 or OH group is to the right, the configuration is assigned as D; if to the left, the assignment is L. If necessary, the modifications D_g and D_s are used to emphasize a relationship with D-glyceraldehyde or D-serine. D/L descriptors refer only to configurations and not to optical rotation. The classical 20 protein amino acids have the same L-configuration

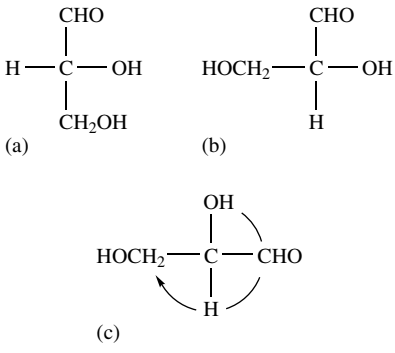

Fig. 2 Transformation of projection formulae. The structure drawn is that of (+)-glyceraldehyde. One interchange of two groups, (a) → (b), inverts the configuration, and a second, (b) → (c), restores the original configuration. As shown in (c), (+)-glyceraldehyde has the (*R*) configuration.

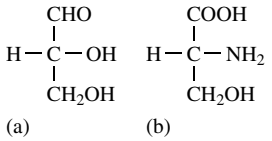

Fig. 3 Configurational standards. (a) = D-glyceraldehyde [also (*R*), see Fig. 2] and (b) = D-serine.

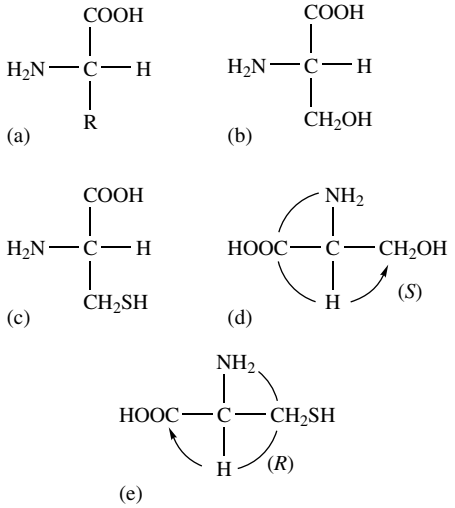

Fig. 4 Amino acid configurations. (a) = L-configuration of the 19 chiral, protein amino acids: R indicates the side chains; (b) = L-serine; (c) = L-cysteine; (d) = L-serine; also (*S*)-serine; (e) = L-cysteine, also (*R*)-cysteine.

(Fig. 4a). As indicated, L-serine also has the (*S*) configuration (Fig. 4b, d). Because of the vagaries of the sequence rule, not all L-amino acids are (*S*); for instance, L-cysteine has (*R*) configuration (Fig. 4c, e).

Carbohydrates have multiple carbon atoms carrying H and OH groups. D/L assignments are based on the arrangement in a projection formula of the H and OH groups at the highest numbered chiral carbon; the numbering starts with the most oxidized group, CHO, C-1 (Fig. 5). Projection formulae for carbohydrates are not informative since the linear carbon chain would normally have a zigzag arrangement; they were devised many decades before computer drawing programs for chemical structures were available. More realistic representations use either vertical or horizontal zigzag carbon chains (Fig. 5d, e). Since carbohydrates usually adopt cyclic structures in aqueous solutions, alternate structures are necessary (e.g. Haworth or Mills structures).

2.3 Axial Chirality

The chirality type so far described is termed *central chirality*. Another type, axial chirality, occurs in planar structures and in compounds of the allene type, abC=C=Cab. Some natural products are allenes; one example is mycomycin: $HC{\equiv}C{-}C{\equiv}C{-}CH{=}C{=}CH{-}CH{=}CH{-}CH{=}CH{-}CH_2{-}COOH$. This compound is a toxic antibiotic. Moreover, a sex attractant for male Dried Bean beetles is $CH_3{-}(CH_2)_6{-}CH_2{-}CH{=}C{=}CH{-}CH{=}CH{-}COOCH_3$. Grasshopper ketone,

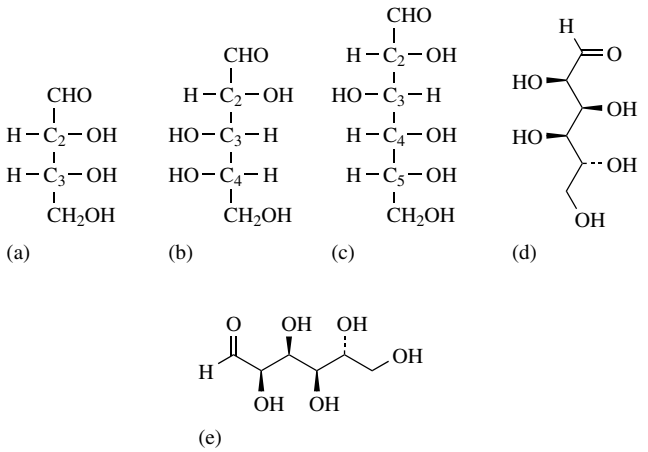

Fig. 5 Carbohydrate configurations. (a) = D-erythrose; (b) = L-arabinose; (c) = D-glucose. The D/L assignments are based on the configurations at C-3 for (a), C-4 for (b), and C-5 for (c); these are the chiral carbon atoms with the highest number. For D-glucose, zigzag configurations are shown as (d) (vertical) and (e) (horizontal).

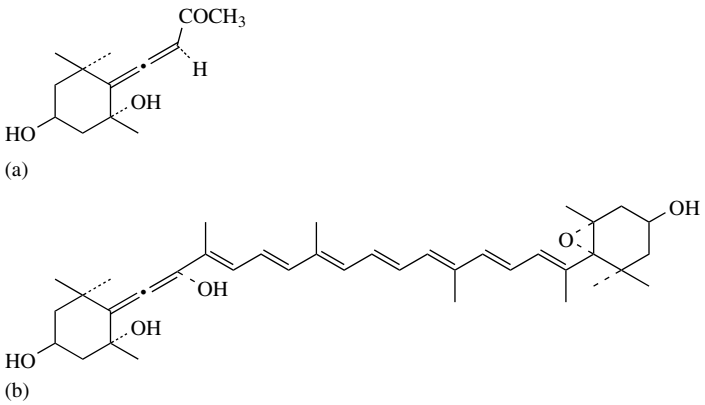

Fig. 6 Naturally occurring allenes. (a) = "grasshopper ketone"; (b) = neoxanthin (from *Lycopersicon* roots).

(Fig. 6a), is used by flightless grasshoppers to repel predatory ants.

Certain carotenoids such as neoxanthin (Fig. 6b) are allenes. Some eicosanoids form allene oxides from fatty acid hydroperoxides by the action of allene oxide synthase (EC 4.2.1.92, hydroperoxide dehydratase). In turn, these allene oxides can undergo cyclization to cyclopentenone derivatives by allene oxide cyclase (EC 5.3.99.6). A specific example of an allene oxide pathway is the biosynthesis of jasmonic acid from α-linolenic acid (Fig. 7). Certain tertiary α-allenic amines inhibit mitochondrial monoamine oxidase type B and the allene group chirality has

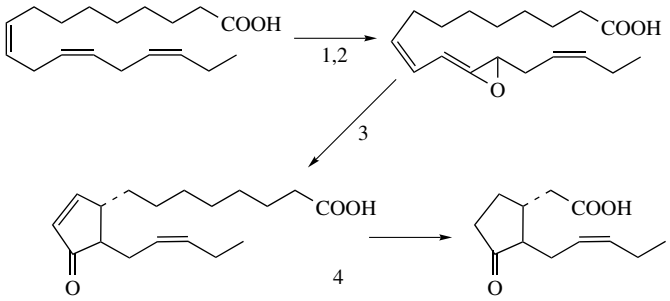

Fig. 7 Biosynthesis of jasmonic acid from α-linolenic acid via an allene oxide. Enzymes are (1) lipoxygenase; (2) allene oxide synthase; (3) allene oxide cyclase; (4) reduction and β-oxidation.

a profound action on the inactivation rate; (*R*)-allenes are up to 200-fold more potent than the (*S*)-allenes.

2.4 Amino Acids

Our biological world is often described as homochiral – thus, the protein amino acids belong to the L configurational series. If only weight is considered, this is certainly true since the tonnage of L-amino acids found in protein is overwhelming; about 18% of the wet weight of a mammal is protein. Of the 20 ''classical'' amino acids involved in ribosomal protein synthesis, glycine is achiral, 17 contain a single chiral center at the α-position, and threonine and isoleucine contain a second chiral center. The necessary aminoacyl-tRNA ligase enzymes are generally very specific for L-amino acids during protein synthesis. When examined *in vitro*, some reactivity with D-amino acids has been observed; for example, the tyr-tRNA ligase from *Escherichia coli* can utilize D-tyrosine.

The so-called 21st ribosomally incorporated amino acid is selenocysteine, $HSe-CH_2-CH(NH_2)-COOH$, found in bacteria, eukaryotes, Archae, and animals. Its formation is complex involving a unique material, $tRNA^{Sec}$. This is ligated with L-serine and the L-seryl-$tRNA^{Sec}$ is converted to selenocysteinyl-$tRNA^{Sec}$ with the aid of selenophosphate. Chirality at the α-position of L-serine is apparently lost in this pyridoxal phosphate-dependent process, but it is usually assumed that the selenocysteine in protein has the L-configuration. A 22nd ribosomally incorporated amino acid, pyrrolysine, present in certain Archae and eubacteria, is $HOOC-CH(NH_2)-(CH_2)_4-NH-CO-R$ (R is apparently (4*R*,5*R*)-4-substituted-pyrroline-5-carboxylate). The R group is attached via the carboxyl group at the $\varepsilon-NH_2$ of lysine. The substituent at position 4 could be methyl, ammonium, or hydroxyl. This amino acid is clearly of the L-configuration, derived from L-lysine. The pyrroline ring structure may be related to D-proline.

Some posttranslational racemization of L- to D-amino acids is possible in proteins. In long-lived proteins, such as lens crystallins, tooth dentine and enamel, and brain myelin, aspartate and serine racemize at a rate of about 0.15% per annum (for aspartate). This process can be used to determine the age of fossil proteins and of long-lived animals if care is taken to

prevent or correct for racemization during isolation.

Posttranslational modification also occurs in the synthesis of the heptapeptide, dermorphin, obtained from skin secretions of certain frogs. An all-L peptide is formed initially by the ribosomal mechanism but an L-alanine residue is converted to D-alanine, probably by dehydrogenation and rehydrogenation, to yield L-Tyr-D-Ala-L-Phe-Gly-L-Tyr-L-Pro-L-Ser (NH_2). The opioid activity of this peptide is greater than that of morphine. Similarly, ribosomally produced lantibiotics (from gram-positive bacteria) contain D-alanine and D-aminobutyric acid units. The material nisin, approved for use as a food preservative, contains 10 of 34 amino acid residues as one lanthionine unit and four β-methyllanthionine units. These units have the following structures; if R = H, the material is lanthionine and if R = CH_3, it is β-methyllanthione. The starred chiral center (*) has the D-configuration: HOOC$-$C*H(NH_2)$-$CH(R)$-$S$-$$CH_2$$-$CH($NH_2$)$-$COOH. These D-residues may derive from L-serine (lanthionine) and L-threonine (β-methyl-lanthione) by dehydrogenation to dehydroalanine and dehydrobutyrine residues respectively, followed by addition of L-cysteine. The L-configuration is lost in the dehydrogenation and L-cysteine addition results in the formation of a D-configuration.

Serine has unusual roles. Several membrane proteins are ''glutamate receptors'' and mediate the effects of this amino acid in neurotransmission. One group termed *N*-methyl-D-aspartate (NMDA – see later) receptors plays a role in memory acquisition, learning, and neurological disorders. Both glycine and D-serine bind to the NMDA receptor. In brain, D-serine is formed by the action of a serine racemase, a pyridoxal phosphate-dependent protein. This brain racemase has been cloned from astrocytes and it is now clear that D-serine has an important role as a neurotransmitter. The incubation of D-serine-containing neurons with D-amino acid oxidase to destroy D-serine greatly reduces the activation of the NMDA receptor. The racemase activity requires divalent cations (e.g. Ca^{2+}, Mg^{2+}), and Ca^{2+} may regulate serine racemase activity. In mutant mice lacking D-amino acid oxidase activity, high levels of D-serine were observed in the forebrain (100–400 nmol g wet tissue^{-1}) with only low levels in the pituitary and pineal glands. The D-serine levels in the cerebellum and the medulla oblongata were 10-fold greater in mutants than in controls. For D-alanine, the levels in mutant mice were higher than those in controls for all brain regions.

Important roles are becoming apparent for D-aspartate. It had been used as a probe for high-affinity L-glutamate/L-aspartate uptake sites and in studies of L-glutamate transport. Its *N*-methyl derivative, *N*-methyl-D-aspartate (NMDA), was known to activate the NMDA receptors. These phenomena were treated as ''unphysiological'' since in mammalian metabolism, D-amino acids were regarded as ''unnatural''. However, free D-aspartate has now been found in the tissues of many invertebrates and vertebrates. It occurs in nervous tissues (chicken, rat, human), in embryo and adult brain and cerebrospinal fluid (humans), and in the pituitary gland and gonads (many mammals). One of the highest observed levels of D-aspartate, 114 ± 18 nmol g wet tissue^{-1}, was in rat adenohypophysis gland; high levels are also present in embryonic tissue.

NMDA itself has now been identified in neuroendocrine tissues. Previously, it was known to be present in the bivalve, *Scapharca broughtonii*. The NMDA levels in

rat nervous tissues and endocrine glands increase following administration of D-aspartate. Experiments with homogenates have shown an enzymatic methyl group transfer from *S*-adenosylmethionine to D-aspartate yielding NMDA. The highest level of transferase activity was in the hypothalamus with significant levels in rat hippocampus, adenohypophysis, brain, and liver.

D-aspartate and NMDA may influence hormone release in various cells. In the case of prolactin (PRL) and the prolactin releasing factor (PRF), NMDA, synthesized in both brain and hypothalamus, stimulates the release of PRF in the hypothalamus. In turn, PRL is then released in the hypophysis. D-aspartate also acts directly on the adenohypophysis, further reinforcing PRL release. D-aspartate occurs at the level of 120 nmol mL^{-1} in testicular venous blood plasma with lower levels in other components; the values are all higher than those for peripheral blood plasma (6 nmol mL^{-1}). The distribution of D-aspartate in rat testes is quite different from that of testosterone. The role of D-aspartate in the male reproductive tract remains unclear, although it may be involved in steroid synthesis in rat testis.

D-Enantiomers of several amino acids occur in various species of hyperthermophilic *Archaea* (e.g. species of *Desulfurococcus*, *Pyrococcus*, and *Thermococcus*). Remarkably, in the case of aspartate, almost 50% of the total content was the D-enantiomer (for the ratio, D-aspartate/total D- + L-aspartate, values ranged from 43.0 to 49.1%). Significant levels of racemization were also observed for alanine, leucine, lysine, and phenylalanine. Aspartate racemase activity was detected in crude extracts from various strains and an aspartate racemase gene was cloned and sequenced from *Thermococcus sp*. strain KS-8. Since peptidoglycan – a usual source of bacterial D-alanine (see below) – is not present in the *Archaea*, the function of D-amino acid enantiomers in these organisms is unclear. Several D-amino acids occur in insects. D-Alanine is present in hemolymph of milkweed bugs (*Oncopeltus fasciatus*), and free and combined forms of D-serine occur in silkworms and earthworms.

D-Amino acids function in the complex structures of some bacterial cell walls. These peptidoglycans (mureins) are polysaccharides with alternating units of *N*-acetyl-D-glucosamine and *N*-acetylmuramic acid. The latter units are linked to a tetrapeptide containing at least one D-amino acid. In *Staphylococcus aureus*, the tetrapeptide is L-ala-D-isoglu-L-lys-D-ala (in isoglutamate, the peptide bond is formed with the γ-carboxyl group). In *E. coli*, *meso*-diaminopimelate replaces L-lysine, and depending on the specific organism, other variations are possible. The capsular substance of anthrax bacillus (*Bacillus anthracis*), *Bacillus subtilis*, and other bacteria consists entirely of poly-D-glutamate.

D-Amino acids also occur in relatively small peptides and related structures produced by microorganisms, for example, penicillin, in which the penicillamine unit ($\beta\beta$-dimethylcysteine) has the D-configuration. Penicillin has three chiral centers; two of them derive from a tripeptide precursor, δ(L-α-aminoadipoyl)-L-cys-D-valine. The gramicidins are antibiotic bacterial peptides synthesized by a multienzyme complex rather than by the ribosomal mechanism. In gramicidin A, a channel-forming ionophore, the peptide chain, contains 15 amino acid residues; with the exception of an achiral glycine unit, units with D- and L-configurations

alternate:

L-Val-Gly-L-Ala-D-Leu-L-Ala-D-Val-L-Val-

D-Val-(L-Trp-D-Leu)$_3$-L-Trp

The N-terminal L-valine is modified by a formyl group and the C-terminal L-tryptophan by ethanolamine. In the antibiotic, actinomycin D (*Streptomyces* strains) there are two D-valine components and the unusual amino acids, sarcosine, and *N*-methyl-valine. Bacitracin A, produced by *B. subtilis* and *B. licheniformis* and present in some nonprescription antibiotic creams, is a dodecapeptide with 4 D-amino acids (aspartate, glutamate, ornithine, phenylalanine). A very simple antibiotic with a single chiral center is D-cycloserine (D-4-amino-3-isoxazolidinone), $C_3H_6N_2O_2$. It is produced by a *Streptomycete sp.*, ultimately from L-serine by way of a ureido derivative:

L-Ser $\rightarrow\rightarrow$ *O*-ureido-L-ser $\rightarrow$

O-ureido-D-ser $\rightarrow$ D-cycloserine.

2.5 Carbohydrates

Carbohydrates are also cited as examples of homochirality. Again, the sheer weight of D-glucose, D-ribose, and D-deoxyribose on planet Earth is enormous; however, there are substantial amounts of some L-carbohydrates, for example, L-arabinose. There have been several chemical or biochemical syntheses of ''unnatural'' carbohydrates, for example, L-glucose, L-galactose, and L-ribose. A biochemical method involves the use of D-galactose oxidase, EC 1.1.3.9. The type reaction is the oxidation of D-galactose at C-6, thus producing D-*galacto*-hexodialdose and H_2O_2, but some other alcohols are oxidized. To prepare L-galactose, the *meso* compound, galactitol (Fig. 8b, $R^1 = OH$, $R^2 = H$) is derived by reduction of D-galactose (Fig. 8a, $R^1 = OH$, $R^2 = H$). Treatment of galactitol with galactose oxidase yields L-galactose (Fig. 8c, $R^1 = OH$, $R^2 = H$). This provides a two-step racemization, D-galactose $\rightarrow$ L-galactose. Oxidation of L(+)-glucitol (Fig. 8b, $R^1 = H$, $R^2 = OH$) yields L-glucose (Fig. 8c, $R^1 = H$, $R^2 = OH$). L(+)-glucitol is prepared by reduction of the readily available D-gulonolactone (Fig. 8a, $R^1 = H$, $R^2 = OH$). The oxidation efficiencies were increased by addition of catalytic amounts of ferricyanide.

L-Glucose has, apparently, not been isolated as a natural product; however, some microorganisms can oxidize it. Very few physiological actions have been attributed to it or its derivatives. Thus, penta-*O*-acetyl-β-L-glucopyranose caused a biphasic increase in plasma insulin concentration

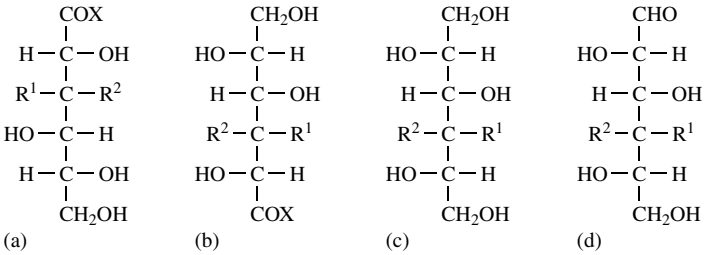

Fig. 8 Synthesis of L-galactose and L-glucose. In the second structure from the left, (a) has been rotated through 180°. See text for details.

when injected into anesthetized rats. In mice, L-glucose increased production of advanced glycation end products and there was accelerated aging. Mice injected with L-glucose also showed an improved memory effect reversed by peripherally acting cholinergic drugs. The L-glucose effect may involve facilitation of acetylcholine synthesis and/or its release. Commercially available L-glucose is used as a nonmetabolizable analog for D-glucose in transport and other metabolic studies. The derivative, *N*-methyl-L-glucosamine, is a component of streptomycin and is biosynthesized from D-glucose.

D-Galactose predominates with L-galactose derivatives in some polysaccharides. The gelling material, agar-agar, contains about 70% of agarose. In this heteropolymer, units with D- and L-configurations alternate; the two monomers are β-D-galactopyranose and 3,6-anhydro-α-L-galactopyranose. Liganded agarose derivatives are used in affinity chromatography. L-Galactose has a role in ascorbic acid biosynthesis in plants (see later). Both enantiomers of 6-deoxygalactose, trivial name fucose, occur widely – D-fucose in plant glycosides and L-fucose in seaweed polysaccharides and in the cell wall matrix of higher plants. L-Fucosyl residues are also present in animal glycoproteins and glycolipids including human erythrocyte surface antigens.

Among other hexoses and their derivatives, residues of L-iduronic acid are present in chondroitin sulfate B (dermatan sulfate), a glycosaminoglycan present in ground substances, connective tissue, and so on; a second component is *N*-acetyl-D-galactosamine. Alginic acid – a hydrophilic polysaccharide found in brown seaweeds, especially the California giant kelp (*Macrocystis pyrifera*) and horsetail kelp (*Laminaria digitata*) – has a complex interrupted structure of stretches of α-L-gulopyranosyluronic acid and β-D-mannopyranosyluronic acid residues. The sodium salt is used extensively as an emulsifier and thickener.

The rather rare 6-deoxytalose, 6-deoxy-3-*O*-methylglucose, and fucosamine occur as both enantiomeric forms. In two cases, enantiomers have different trivial names; the D- and L-forms of 3,6-dideoxygalactose are respectively abequose (*Salmonella* lipopolysaccharides) and colitose (*E. coli* lipopolysaccharides). The corresponding forms of 3,6-dideoxymannose are tyvelose (lipopolysaccharides of some gram-negative bacteria) and ascarylose (a glycolipid component in *Ascaris* eggs and *Yersinia pseudotuberculosis*).

The pentoses, D-ribose and 2-deoxy-D-ribose, occur in large amounts in nucleic acid structures. Although generally assumed not to occur in nature, isolation of L-ribose from water-soluble polysaccharides of *Adonis vernalis* (pheasant's eye, ox's eye) has been reported. Mutants of *E. coli* and some other bacteria metabolize L-ribose by an NADPH-linked reductase to ribitol; subsequently, ribitol pathway enzymes convert ribitol to D-ribulose (D-*erythro*-pentulose). An L-ribose isomerase, converting L-ribose to L-ribulose (L-*erythro*-pentulose), has been isolated from *Acinetobacter sp*. The gene for this enzyme was cloned into *E. coli* and sequenced; the recombinant enzyme was purified to homogeneity. Further metabolism presumably involved the pentose phosphate phosphoketolase pathway: L-ribulose $\rightarrow$ L-ribulose 5-phosphate $\rightarrow$ D-xylulose 5-phosphate $\rightarrow$ acetyl phosphate + glyceraldehyde 3-phosphate.

The next most abundant pentose is D-xylose, present in the xylans; xylan is the

next most abundant carbohydrate after cellulose. The rare L-xylose occurs in some antibiotics and lipopolysaccharides (e.g. of *Xanthomonas campestris*). With arabinose, the L-enantiomer is common in many plant products (e.g. gums, hemicelluloses, and glycosides) and in bacterial polysaccharides. The also-rare D-enantiomer occurs in some plant glycosides and bacterial polysaccharides. D-Lyxose is very rare but is present in alkali-labile glycolipids of *Mycobacterium smegmatis*. Naturally occurring derivatives of L-lyxose are 2-*O*-methyl-lyxose, a component of antibiotics such as everninomycin B and D, and 3-*O*-methyl-lyxose, present in lipopolysaccharides of *Pseudomonas maltophilia*. The streptomycin component, L-streptose, is 5-deoxy-3-formyl-L-lyxose, and a material in *Coxiella burnettii* lipopolysaccharides is 3-*C*-hydroxymethyl-L-lyxose (dihydrodihydroxystreptose). Some strains of *E. coli* utilize the lyxose enantiomers. One microorganism, *Aerobacter aerogenes* strain PRL-R3, utilizes all eight aldopentoses (i.e. four each of the D- and L-configurations) and the four pentitols (D- and L-arabinitol, ribitol, xylitol) as well.

Vitamin C (L-ascorbic acid, 2-keto-L-gulono-γ-lactone) occurs only as the L-enantiomer. It is biosynthesized in plants by way of L-galactose as follows: D-glucose 6-phosphate → GDP-D-mannose → GDP-L-galactose → L-galactose 1-phosphate → L-galactose → L-galactono-1,4-lactone → L-ascorbic acid. *Saccharomyces cerevisiae* synthesizes L-ascorbic acid when incubated with L-galactose, L-galactono-1,4-lactone, and L-gulono-1,4-lactone. However, incubation with D-glucose, D-galactose, D-mannose, or D-arabinose gave D-erythroascorbic acid, a five-carbon analog of L-ascorbic acid.

Animals use a different pathway to make vitamin C and in some, the capacity is lacking (e.g. primates and guinea pigs). In the rat, conversion of D-glucose to L-ascorbic acid requires ''inversion'' of the carbon chain sequence so that C_1 to C_6 of D-glucose appear as C_6 through C_1 in ascorbate.

2.6 Other Natural Products

Many natural products occur both as enantiomers and, sometimes, as racemates or *meso* structures; only a few examples can be given. The case of tartaric acid is typical. In the nineteenth century, a material named paratartaric acid was sometimes formed in wine production, and Pasteur separated crystals of sodium ammonium paratartrate into two enantiomorphic forms by ''crystal picking.'' One of the free tartaric acids obtained from the salts was dextrorotatory, the other levorotatory. In other words, paratartaric acid was a racemic DL mixture. The L(+) (or 2*R*,3*R*) enantiomer is found in some fungi and bacteria and is particularly abundant in grape juice. The D(−) (or 2*S*,S3) enantiomer and the *meso* form have limited distribution.

Lactic acid formed in muscle glycolysis is the L(+) enantiomer, (*S*)-(+)-2-hydroxypropanoic acid. D(−)-lactic acid is present in bacteria as the peptidoglycan component, *N*-acetylmuramic acid, muramic acid being the 3-*O*-D-lactyl ether of D-glucosamine. Racemic DL acid is found in sour milk, molasses, and some fruit juices. Bacterial lactate fermentations produce either the D- or L-enantiomer or the racemate depending on the organisms used.

Alkaloids, terpenes, and many other secondary metabolites frequently occur in both enantiomeric forms or as racemates. Examples of alkaloids that occur as (+), (−), and racemic forms are the tobacco

alkaloid, nornicotine, and the lupinane alkaloids, lupanine and sparteine. The important alkaloid, reticuline, is involved in a number of biosynthetic processes. (*S*)-(+)-Reticuline occurs in *Anona reticulata* and other plants and is an intermediate for biosynthesis of, among others, berberine, chelidonine, laudanosine, and narcotine. *Papaver somniferum* contains both enantiomers depending on the age of the plants, and (*R*)-(−)-reticuline is the major precursor in morphine alkaloid biosynthesis.

Among terpenes, it is almost the rule rather than the exception for materials to occur in enantiomeric and/or racemic forms. Common materials such as borneol, camphor, carvone, citronellol, fenchone, limonene, menthol, pinene, and terpineol occur as both enantiomers; racemates are known for borneol, camphor, and limonene. Some biosynthetic information is available. Purified enzymes from sage (*Salvia officinalis*) and tansy (*Tanacetum vulgare*) convert achiral geranyl bisphosphate to a linalyl bisphosphate, LPP, probably as an enzyme-bound intermediate. The sage system forms (3*R*)-(−)-LPP and tansy, (3*S*)-(+)-LPP. Subsequently, (3*R*)-(−)-LPP is converted to (1*R*,4*R*)-(+)-bornyl bisphosphate and the (3*S*)-(+)-LPP to the (1*S*,4*S*) enantiomer. Hydrolysis of the bisphosphates yields the two enantiomeric borneols. Two further enzymes from sage form enantiomeric pinenes. The (+)-pinene cyclase converts achiral geranyl bisphosphate to (+)-α-pinene and (+)-camphene, and the (−)-pinene cyclase forms mainly (−)-α-pinene, (−)-β-pinene and (−)-camphene.

Since racemization may occur during isolation of chiral natural products, precautions are necessary. Hyoscyamine readily undergoes racemization in the tropic acid component and partial racemization occurs during isolation. For pharmaceutical use, racemization is completed by alkali treatment yielding the widely used atropine (racemic hyoscyamine containing (±)-tropic acid). The mydriatic action resides only in the (−)-tropic acid component.

A few natural products are "quasi-racemates," a mixture of equimolar amounts of two substances with slightly different structures and of opposite chirality. An early example was a benzoquinone from *Dalbergia nigra* (Fig. 9a, b). Narcisamine, from King Alfred daffodils, was a quasi-racemate of (−)-demethylgalantha-

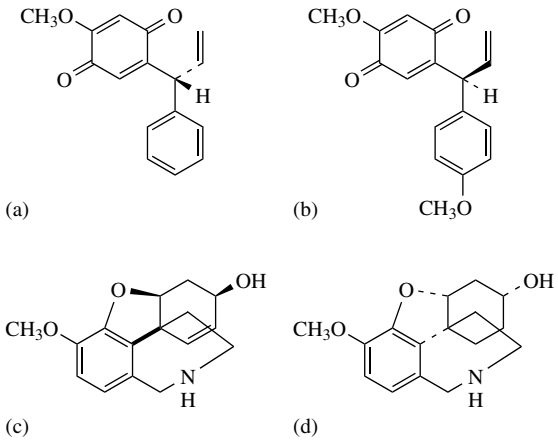

Fig. 9 Naturally occurring quasi-racemates. (a), (b) = benzoquinone from *Dalbergia nigra*; (c), (d) = narcissamine from King Alfred daffodils.

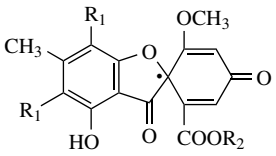

Fig. 10 Spiro polyketide metabolites. The chiral, spiro carbon is indicated by the symbol ..

mine and (+)-demethyldihydrogalanthamine (Fig. 9c, d).

In some polyketide metabolites of fungi, the chiral center is a spiro carbon atom (Fig. 10). When $R_1 = Cl$, $R_2 = H$, the compound is named *erdin* and occurs as a racemate in *Aspergillus terreus*; this organism also produces geodin, $R_1 = Cl$, $R_2 = CH_3$, as the (+) enantiomer. Bisdechlorogeodin, $R_1 = H$, $R_2 = CH_3$, occurs as the (+) enantiomer in *Penicillium frequentans* and as the (−) enantiomer in *Oospora sulfurea-ochracea*.

3 Physiological Responses to Enantiomers

Of the human senses, probably only hearing lacks a connection with chirality. Enantiomeric differences are common for taste and smell, and sight and touch can detect mirror-image relationships.

3.1 Taste

Classically, taste qualities in mammals included sweet, bitter, salty, and sour. The quality ''umami'' has now been added, describing the meatlike, savory taste of L-glutamate. Enantiomeric taste differences for amino acids were first noted in 1886 when D-asparagine was found to be sweet, while L-asparagine was tasteless. For the following, the D-enantiomers are sweet, the L-forms being bitter or flat: histidine leucine, phenylalanine, tryptophan, and tyrosine. Alanine is an exception since the L-enantiomer is sweet. Arginine, aspartate, isoleucine, lysine, proline, serine, and threonine are essentially tasteless, for both enantiomers. Achiral glycine is sweet as the name implies.

The remarkable umami taste is responsible for much of the flavor of soy sauce and monosodium L-glutamate, MSG, which is widely used in the food industries. In amounts greater than about 3.0 g, L-glutamate may show other physiological effects since some individuals experience the ''Chinese restaurant syndrome'' – a general feeling of tightness, facial pressure, burning sensations, and headache. In contrast, D-glutamate with at most a flat taste is relatively inert physiologically.

Another remarkable taste quality is that of the methyl ester of *N*-L-α-aspartyl-L-phenylalanine (trade name, Aspartame), a material some 160 times as sweet as sucrose. Interestingly, rodents do not react to Aspartame. It is widely used but should be avoided by individuals with phenylketonuria. The DD enantiomer, as well as the DL and LD diastereoisomers have bitter tastes.

Specific taste receptors have been identified in humans and animals. Receptors designated as TRB (taste receptor, family B) are G-protein-coupled receptors (GPCR); human receptors were identified by searching for GPCR-encoding genes in human genome regions implicated in taste perception.

A receptor in mammals, designated T1R1 +3, is a heteromer of the taste-specific T1R1 and T1R3 GPCRs. This receptor responds to the classical 19 chiral amino acids as L- but not D-forms, and the effect is potentiated by IMP; it is probably a constituent of the umami response. Sequence differences in T1R receptors between human and mouse influence the selectivity and specificity of the taste response. A different receptor, T1R2 +3 is activated by those D-amino acids that taste sweet and attract mice; L-amino acids did not cause this activation.

A complex system occurs in a preparation from catfish (*Ictalurus punctatus*) taste epithelium where L-alanine is a potent taste stimulus; D-alanine has a lesser effect. For a portion of the observed response, there may be a common receptor/transduction process, but in addition there appear to be independent processes for each enantiomer. The Caribbean spiny lobster (*Panulirus argus*) contains populations of chemosensory receptors that are differentially sensitive to D- and L-alanine. Of 77 neurons tested, 44% and 34% were classified as L-alanine and D-alanine-sensitive respectively.

Taste differences are generally rather subtle, especially for carbohydrates. While sucrose might be regarded as the epitome of sweet substances, it has been reported that ''at the threshold level, sucrose yields a tactual sensation, which may be called bitter, medicinal, sour, and so on, but as the concentration is increased, the taste becomes bitter, then bitter-sweet, and finally, purely sweet.'' Apparently, ''enantio-sucrose'' (containing L-glucose and L-fructose) has never been prepared or tasted. Carbohydrate solutions are generally complex equilibrium mixtures of anomeric pyranose/furanose and straight-chain forms. Some taste differences for anomers and equilibrium solutions are known. There are also temperature and concentration effects (e.g. with sucrose) and considerable variation from one individual to another.

There is no strong evidence for general enantiomeric differences among carbohydrates. Thus, L-mannose was rated less sweet than D-mannose by five individuals, but three others said the reverse and still others found D-mannose to be bitter. Identical ''sweetness scores'' have been claimed for enantiomers of glucose, mannose, galactose, fructose, and xylose. In fact, there have been proposals to use L-hexoses as nonnutritive sweetners. While syntheses for L-glucose are available (see earlier) they are presumably too expensive to compete with materials such as aspartame. Penta-*O*-acetyl derivatives of various monosaccharides are not sweet; the following were actually rated as bitter: penta-*O*-acetyl-D-glucose (both anomers), penta-*O*-acetyl-α-D-mannopyranose, and penta-*O*-acetyl-β-L-glucopyranose.

''Pseudo''-carbohydrates, in which $-CH_2-$ replaces $-O-$ in the ring structure, also have sweet tastes, but again, there are ambiguities. Five people found the enantiomers of pseudo-β-fructopyranose to be as sweet as ordinary D-fructose; three out of five judged the D-enantiomer to be somewhat sweeter than the L. The thiopyranoid analogs of α-D-glucopyranose and β-D-fructopyranose are significantly sweeter than the usual forms.

3.2 Odor

The subject of enantiomeric odor differences has been controversial. Unfortunately, there is considerable variation in human olfactory sensitivity, and the nose is generally very sensitive to small

levels of impurities in materials under investigation. Testing differences also arise from variations in individual physiology, past experience with a given odor, and fatigue among members of a testing panel. Nevertheless, careful experiments have established a spearmint odor for (*R*)-carvone and a caraway odor for (*S*)-carvone. These materials are the major components of respectively oil of peppermint and oil of caraway. Important evidence was obtained by ingenious chemical inversions of one enantiomer into the other, the inversions resulting in very specific changes of odor; one sequence was (*R*)-(−)-carvone (spearmint) → (*S*)-(+)-carvone (caraway) → (*R*)-(−)-carvone (spearmint). The inversion was repeated similarly, starting with (*S*)-(+)-carvone.

Recent, careful testing has confirmed that the carvone enantiomers are distinguishable by odor, and this was also true for enantiomers of α-pinene and limonene. Most members of this panel (20 subjects), however, could not distinguish enantiomers of 2-butanol, camphor, β-citronellol, fenchone, menthol, rose oxide, and α-terpineol. The discriminatory ability between enantiomers is apparently substance-specific and is not a general phenomenon. There are probably specific enantioselective odor receptors for some but not all volatile enantiomers. Squirrel monkeys showed discriminatory abilities similar to those of humans; unlike humans, they could distinguish the fenchone enantiomers.

Rats readily discriminated the carvone enantiomers and, unlike humans, also distinguished enantiomers of fenchone, 2-butanol, and 2-octanol. In a study of the rat olfactory bulb, each enantiomer produced a widespread and distinct pattern of active glomeruli. Each member of an enantiomeric pair preferentially activated one or more glomeruli. In mole rats (*Spalax ehrenbergi*), some differential responses were observed to enantiomers of carvone, citronellol, and fenchone. The animals responded to one enantiomer but were indifferent to or did not smell the other [(*S*)-(+)-carvone, (−)-citronellol, (+)-fenchone]. (*R*)-(−)-Carvone was attractive to both sexes and females were attracted to (−)-fenchone. Both sexes were repelled by (+)-citronellol. Free-flying honeybees discriminated carvone, β-citronellol, limonene, menthol, and α-pinene enantiomers but not those of 2-butanol, camphor, fenchone, rose oxide, and α-terpineol.

For the *cis*-methyl jasmonates, two diastereoisomeric pairs have been tested (Fig. 11). Only the (3*R*,7*S*) and (3*R*,7*R*) diastereoisomers have an odor described as ''typically floral, jasminic, slightly fruity,'' and the odor of natural ''methyl jasmonate'' is due largely to the (3*R*,7*S*)-(+) material (Fig. 11a). The (3*S*,7*R*) and (3*S*,7*S*) materials were odorless.

The ''musk'' odor is important in perfumery, and several synthetic odorants are used commercially. For the naturally occurring (3*R*)-(−)-muscone (Fig. 11b), the musk note was ''very nice, rich, and powerful'' but for the enantiomer, (3*S*)-(+)-muscone, the note was ''poor and less strong.'' The compound shown in Fig. 11(d) ''has an animalic tonality with camphoraceous aspects,'' while the enantiomer (Fig. 11e) had a musk note ''with a sandalwood tonality.'' Both are found in *Angelica* root oil in a ratio of 29 : 72 for structures (d) and (e) (Fig. 11). In another case, (12*R*,9Z)-12-methyl-14-tetradec-9-enolide (trade name, Nirvanolide, Fig. 11c) possessed an ''intense musky, fruity, powdery odor with lactonic nuances.'' Its enantiomer was odorless. The commercially important polycyclic

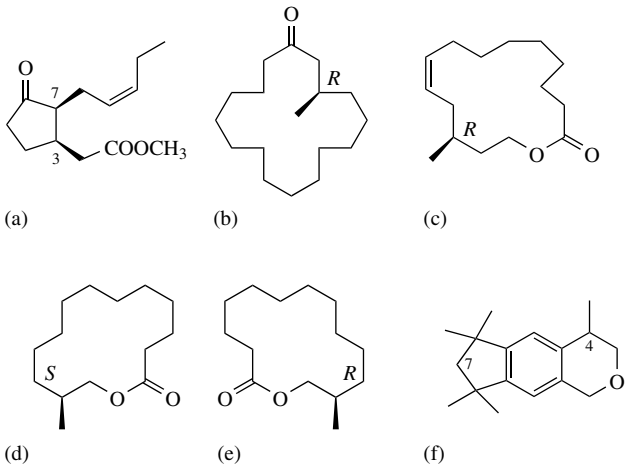

Fig. 11 Enantiomeric fragrances. (a) = (3*R*,7*S*) methyl jasmonate; (b) = (3*R*)-muscone; (c) = (12*R*)-Nirvanolide; (d), (e) = *Angelica* root oil compounds; (f) = Galaxolide.

musk odorant with the trade name Galaxolide (Fig. 11f) has four diastereoisomers rated as follows: (4*S*,7*R*)-(−) – very pleasant musk character; (4*R*,7*S*)-(+) – weak, uncharacteristic; (4*S*,7*S*)-(−) – musky, but dry aspects; and (4*R*,7*R*)-(+) – very weak, mainly fruity.

A new flavor material, 3-mercapto-2-methylpentanol, has an odor described as brothlike, leeklike, and sweaty – quite a combination! It has been isolated from volatiles of raw onions and in some processed foods. With two chiral centers, there are four stereoisomers; while all apparently have the same general odor, there are remarkable differences in their odor thresholds in water and air. The two *anti* enantiomers (2*R*,3*S*) and (2*S*,3*R*) (Fig. 12a) had thresholds in water of 0.03 to 0.04 μg L^{-1}. In air, the (2*R*,3*S*) material has an extremely low threshold, 0.00007 to 0.0002 ng L^{-1} and is ''among the most potent flavor compounds.'' Its less-potent enantiomer has air threshold of 0.003 to 0.007 ng L^{-1}. The air threshold values for the *syn* enantiomers (2*R*,3*R*) and (2*S*,3*S*) (Fig. 12b) could not be determined since they were contaminated with 0.1 to 0.3% of the very potent *anti* compounds.

Another odorant with two chiral centers is ''whiskey lactone,'' 2-methyl-4-octalone, extracted from oak woods during the

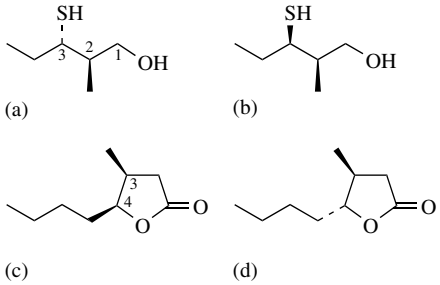

Fig. 12 Enantiomers of 3-mercapto-2-methylpentanol and ''whiskey lactone.'' (a) = *anti* (2*R*,3*S*)-3-mercapto-2-methylpentanol; (b) = *syn* (2*R*,3*R*) diastereoisomer; (c) = (3*S*,4*S*)-2-methyl-4-octalone; (d) = (3*S*,4*R*) diastereoisomer.

aging process for wines and spirits. The major natural odor material is the (3*S*,4*S*)-*cis*-compound (Fig. 12c) with a coconut, lactonelike odor. Some flowery, lactonelike (3*S*,4*R*)-*trans*-component is also present (Fig. 12d). Substitution of one or both oxygen atoms with sulfur gave significant odor changes.

While many enantiomeric odor discriminations involve pleasant, floral, or fruity odors, nature also produces many foul odors. For instance the microbial product, geosmin, *trans*-1,10-dimethyl-*trans*-decalol, is known for its unpleasant moldy, earthy odor, with the (−) enantiomer being more odoriferous than the (+) form. The odor thresholds in water are also very different: (−), 9.5 ± 1.3 ng L^{-1}, and (+), 78 ± 12 ng L^{-1}. Enantio-MGDC analysis (see later) of wines with an earthy odor revealed significant levels of (−)-geosmin. This enantiomer was also found in some grape juices, probably from the growth of microorganisms.

Gas chromatography has been a valuable tool in studying the volatile components of the widely used essential oils. Column packings able to separate enantiomers (''chiral chromatography'') have greatly expanded the scope and value of this technique, as have ''hyphenated'' techniques, using mass spectrometry; for example, enantioselective multidimensional gas-chromatography mass spectrometry (enantio-MDGC-MS), and gas-chromatography pyrolysis-isotope mass spectrometry. One group, using various gas chromatographic techniques, has published a series of papers titled ''Stereoisomeric Flavor Components'' that reached number LXXXII in 1999.

These techniques yield important basic scientific information and have practical applications. By comparing an authentic natural oil sample with other samples, the presence of unnatural, often chemically synthetic, components can be detected. The important lavender oil has several odorants, including linalool and linalyl acetate; (*R*)-(−)-linalool has the characteristic lavender odor, (*S*)-(+)-linalool, has a petitgrain-like odor (i.e. an odor of bitter or sour orange). For these materials, genuine lavender oil must contain at least 85% enantiomeric excess of (*R*)-(−)-linalool and at least 95% enantiomeric excess of (*R*)-(−)-linalyl acetate. In a recent study, five samples of ''lavender oil'' were found to be adulterated with racemic, synthetic materials (see Table 1).

Tab. 1 Enantiospecific analysis of samples of oil of lavender.

Sample	*Linalyl acetate*		*Linalool*	
	(R)	*(S)*	*(R)*	*(S)*
1	52.9[a]	47.1	70.7	29.3
2	55.7	44.3	55.5	44.6
3	51.8	48.2	62.0	38.0
4	52.0	48.0	69.7	30.3
5	53.3	46.7	60.8	39.2
Authentic	95.0 (minimum)		85.0 (minimum)	

[a]The values given are percentage compositions.

Essential oils have been used in folk medicine, and it is a common belief that odors can influence mood, alertness, and sexual arousal (witness the appeal of aromatherapy). Some work concerns the effects of chiral fragrances on the human autonomic nervous system. In one study, inhalation of (+)-limonene (odor is orange) gave increased systolic blood pressure, subjective alertness, and restlessness; inhalation of (−)-limonene (odor is turpentine) increased systolic blood pressure without influencing psychological parameters. Similar responses were obtained with carvone enantiomers. The effects were complex and both pharmacological and psychological mechanisms were probably involved.

In studies of linalool enantiomers, differences in perception and responses elicited by a sensory test and forehead surface potential wave measurements were measured. (*R*)-(−)-linalool, administered after hearing environmental sounds, gave a favorable impression, and there was a tendency for the beta wave to decrease. With (*S*)-(+)-linalool, there was an unfavorable impression and the beta wave increased. Different and complex results were obtained following mental work. These preliminary results showed that the responses to the two enantiomers depended, in addition, on tasks assigned to the subjects.

Enantio-MDGC-MS has been used in some human metabolic studies. Methylcitric acid, MCA, occurs in body fluids of individuals with propionic acidemia, methylmalonic aciduria, or holocarboxylase deficiency. MCA has two chiral centers; of the four possible stereoisomers, only the (2*S*,3*R*) and (2*S*,3*S*) diastereoisomers were detected in patients and controls, in proportions varying from about 30 to 70%. The differences may be due to physiological effects on the citrate synthase enzyme forming MCA from oxaloacetate and propionyl-CoA.

3.3 Insect Pheromones

For chiral insect pheromones, the nature of the chirality generally has a profound effect on the observed physiological response. Thus, with the female spider sex pheromone, 3-hydroxybutyric acid, only the (3*R*) structure is functional. All of the following situations have been observed:

1. As just noted, activity is present in only one enantiomer, the other being indifferent (e.g. (+)-exobrevicomin, pine sawfly pheromone) or inhibitory (e.g. (+)-disparlure, (*S*)-*cis*-verbenol).
2. All stereoisomers are active (e.g. grandisol, seudenol).
3. Different species may differentiate enantiomers, for example, (*S*)-(+)-ipsdienol used by *Ips paraconfusus* and the *R* enantiomer by *I. calligraphus*. A more complex situation occurs with scarab beetles. For *Anomala osakana*, the female produces the male attractant, (*S*,*Z*)-5-(1-decenyl)oxacyclopentan-2-one. However, in *Popillia japonica* the (*R*) enantiomer is attractive to males. These activities are inhibited by the respective enantiomers. In field tests with *A. osakana*, catches of males in traps baited with the (*S*) enantiomer were completely inhibited by as little as 5% of the (*R*) form. The reciprocal behavioral agonist–antagonist situation provides a species-specific chemical signal with the use of a single chiral structure. Interestingly, these two beetles share a common habitat in Japan.

4. Activity may require both enantiomers. For honeybee queen mandibular pheromone (a mixture of compounds), both enantiomers of 9-hydroxy-2-decenoic acid must be present for full activity. Another example is sulcatol.

3.4 Plant Growth Regulators

With chiral plant growth regulators, one enantiomer of a chiral structure is usually the most potent. Thus, for α-phenoxypropionic acid, the (*R*) enantiomer has the most powerful herbicidal activity. The naturally occurring form of abscisic acid is (*S*), and the (*R*) form is significantly less potent in inhibiting root growth of germinating barley; there is little difference between these two enantiomers in other physiological effects. The growth regulator, paclobutrazol (β-[(4-chlorophenyl)-methyl]-α-(1,1-dimethylethyl)-1H-1,2,4-triazole-1-ethanol), also has antifungal activity. Of the four stereoisomers, the most effective in growth regulation is the (2*S*,3*S*)-(−) form (Fig. 13a), whereas the enantiomer (2*R*,3*R*)-(+) is most effective as a fungicide.

Jasmonic acid and its conjugates are plant signaling substances synthesized in response to external stimuli (e.g. wounding). The (3*R*,7*R*)-(−) enantiomer is particularly common (Fig. 13b). In barley leaves, treatment with jasmonic acid yields upregulation of specific genes and downregulation of housekeeping genes. The (−) enantiomers of the methyl ester and amino acid conjugates are more active than the (+) forms; conjugates with an L-amino acid also tend to be more active. The responses of the jasmonate-responsive genes to the various chiral structures are complex.

Physiological effects can vary with different strains of the same plant. For the synthetic auxin indole-3-succinic acid, a 10^{-8} M concentration of the (*R*) enantiomer is most potent as a root growth promoter for the SF (swingtime) strain of *Fuschia hybrida*, with the opposite enantiomer being more potent for the VF (variegated) strain at all concentrations.

3.5 Chiral Drugs

Reactions to pharmaceutical agents may be influenced significantly if chiral elements are present. Early in the twentieth century, enantiomers and racemates of hyoscyamine and epinephrine were distinguished by quantitative differences in their physiological actions. However, there was for many years little concern about the possible impact of chirality on widely used drugs. After World War II, attention was focused on the role of chirality in pharmacology and medicinal chemistry, and there is now an enormous literature including conferences and symposia on the topic of ''chiral drugs.'' For instance, a query to PubMed on this topic

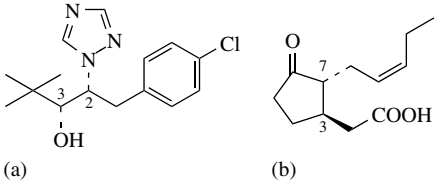

Fig. 13 Chiral plant growth regulators. (a) = (2*S*,3*S*) stereoisomer of paclobutrazol; (b) = (3*R*,7*R*)-jasmonic acid.

in October 2002 elicited 703 ''hits.'' The topic is extremely complex and only a brief account is possible here. A complication is that pharmacologists consider two main areas – pharmacodynamics and pharmacokinetics. The first concerns actual physiological effects caused by a drug and the nature of the binding to receptor sites as well as correlation of chemical structure with physiological activity. Pharmacokinetics concerns differences in the rate of transport of the drug to the receptor sites, in clearance rates, and the possibility of transformation to other products that themselves might or might not have a physiological action.

Medicinal drugs are of three general types: some such as aspirin are achiral and of no concern here; chiral drugs obtained by chemical synthesis are usually racemic mixtures (e.g. fluoxetine, trade name Prozac); chiral drugs obtained from natural sources such as plants or from fermentations are usually single enantiomers (e.g. morphine, penicillin). There has been considerable interest among pharmaceutical companies in developing single-enantiomer forms or in switching from a racemic mixture already in use to a single enantiomer – the so-called *racemic switch* (a racemic switch may also provide a new drug when patents are expiring). The stakes are high. In 2001, worldwide sales of formulated pharmaceutical products totaled $410 billion; single-enantiomer drugs accounted for sales of $147 billion (36%).

In 1992, the US Food and Drug Administration, FDA, issued a policy statement for the development of stereoisomeric drugs that was mainly concerned with chiral drugs and the need for appropriate testing of enantiomers. However, under certain circumstances, the development and use of racemic mixtures was to be allowed. This FDA statement recognized three pharmacodynamic cases:

Case 1. Both drug enantiomers have similar, desirable pharmacological effects. This is the case with ibuprofen, a nonsteroidal antiinflammatory agent, sold as a racemate over the counter under various brand names (e.g. Advil, Motrin, Nuprin). It contains a single chiral center. Both enantiomers are antiinflammatory, but (*S*)-(+)-ibuprofen (Fig. 14a) is the more active and lacks some side effects. A racemic switch has led to the availability of (*S*)-ibuprofen in Austria and Switzerland, but this form was not approved for the United States. Ibuprofen also shows an interesting pharmacokinetic property. During metabolism, the (*R*)-(−) enantiomer undergoes configurational inversion forming the (*S*)-(+)-ibuprofen. Thus, administration of racemic ibuprofen to humans leads to excreted material in which the enantiomer composition is 70% (*S*) and 30% (*R*).

Another Case 1 situation is warfarin. When used as an anticoagulant in humans, the enantiomers are equipotent. However, warfarin is also used as a selective rodenticide, and in this application (*S*)-(−)-warfarin (Fig. 14b) is about 6 to 7 times more potent than the (*R*) form. There may be a pharmacokinetic effect – the (*S*) form has an approximately twofold longer half-life (15.4 ± 2.8 h) than the (*R*) enantiomer.

For the serotonin (5-hydroxytryptamine) uptake inhibitor fluoxetine (trade name, Prozac), both enantiomers also have an almost equipotent blocking action. In this case, there was an economic reason for pursuing a racemic switch – the patent on the racemate began to expire in 2001. With the single-enantiomer (*R*) form (Fig. 14c), there was a small but significant

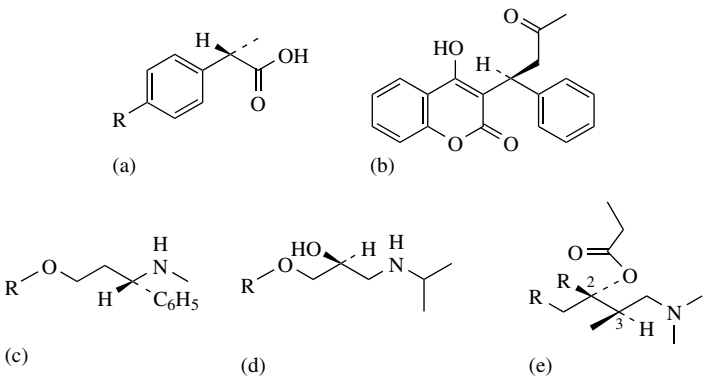

Fig. 14 Chiral drugs. (a) = (*S*)-ibuprofen, R = $CH_3CH(CH_3)CH_2$–; (b) = (*S*)-warfarin; (c) = (*R*)-fluoxetine (trade name, Prozac), R = CF_3-C_6H_4–; (d) = (*S*)-propranolol, R = $C_{10}H_7$–; (e) = (2*R*,3*S*)-propoxyphene (as hydrochloride, trade name Darvon), R = C_6H_5–.

cardiac side effect at high dosage, and development was discontinued.

Case 2. One enantiomer has the desired physiological activity, the other does not. For propranolol, a β-adrenergic blocking agent, the (*S*)-(−) compound (Fig. 14d) is much more effective than the enantiomer; the activity ratio, S : R, is 100 : 1. However, like many drugs, propranolol has other activities. As a local anesthetic, as a regulator of thyroxine metabolism, in membrane stabilization, and for psychiatric use, the enantiomers are equipotent. Propranolol shows complex, enantioselective pharmacokinetic behavior. The (*S*) enantiomer accumulates selectively in the heart with the (*R*) enantiomer remaining largely in blood and being stereoselectively metabolized.

Case 3. The two drug enantiomers have different pharmacological activities one of which may be either desirable or not. Both enantiomers of propoxyphene have useful, different activities. The (2*S*,3*R*)-(+) enantiomer is an analgesic (trade name of hydrochloride, Darvon, Fig. 14e), while the (2*R*,3*S*)-(−) enantiomer is marketed as a naphthalene sulfonate (trade name, Novrad) for use as an antitussive. Darvon read in reverse is Novrad, but the two names are not exact mirror images.

Thalidomide (trade name, Contergan) is often considered as a Case 3 compound but the actual situation is complex. Use of the racemic mixture as a sedative and antinausea agent by pregnant women (although not in the United States) beginning in about 1956 was responsible for the birth of the so-called *thalidomide babies* – worldwide about 10 000 cases of phocomelia – before it was withdrawn from the world market. Early animal work suggested that the teratogenic action was associated with (*S*)-(−) thalidomide (Fig. 15a), which underwent metabolism successively to *N*-phthaloylglutamine (Fig. 15b, R = NH_2) and *N*-phthaloylglutamic acid (Fig. 15b, R = OH). The latter compounds with L(*S*) configurations were teratogenic and the D(*R*) metabolites were harmless. However, this work has apparently never been confirmed independently, and there is a difficulty. Thalidomide undergoes

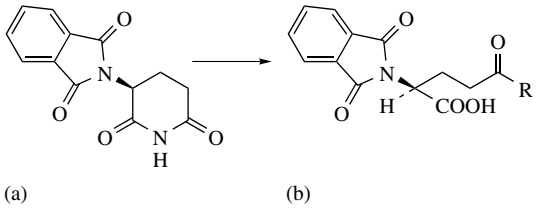

Fig. 15 Thalidomide metabolism. (a) = (*S*)-(−)-thalidomide; (b) = *N*-phthaloyl-L-glutamine, R = NH_2; (b) = *N*-phthaloyl-L-glutamic acid, R = OH.

rather rapid racemization under physiological conditions. In rabbits, for example, thalidomide isolated from plasma 2 h after intravenous injection was completely racemized. It has actually been stated, "that it is practically impossible to demonstrate stereoselectivity in any *in vivo* biological effect of thalidomide" (but see below). With dynamic capillary electrokinetic chromatography, the enantiomerization barrier, $\Delta G^{\#}$, was found to be 102 ± 1 kJ mol^{-1} at pH 8.

Physiological effects of intravenous injection (rather than *per os*) of thalidomide enantiomers into male volunteers have been investigated. Although the enantiomers have low solubility (ca. 0.3 mg mL^{-1}) in 5% glucose (pH 4–5) solutions, preparations were obtained for injections containing 0.2 mg mL^{-1}. [The racemate has lower solubility – 0.07 mg mL^{-1} – and is a likely racemic compound (each crystal contains equal numbers of each enantiomer) rather than a racemic mixture (any crystal contains only one enantiomeric form)]. The solutions formed less than 1% of the opposite enantiomer on 9 days of storage. The results confirmed earlier observations that sedation and sleep were related to blood concentrations of (*R*)- but not (*S*)-thalidomide. Immunological effects (see below) have been attributed to the (*S*) enantiomer. These observations appear to confirm the earlier work assigning teratogenic activity to the (*S*)-(−) enantiomer.

To a surprising extent, racemic thalidomide (only available on prescription) has made a comeback because of immunomodulatory and antiangiogenic properties. It has been used to treat severe recurrent aphthous stomatitis in AIDS patients and to treat systemic manifestations of erythrema nodosum leprosum in patients receiving recombinant interferon-γ treatment for lepromatous leprosy. Moreover, racemic thalidomide inhibits replication of human immunodeficiency virus Type 1 and has a modest ability to inhibit tumor necrosis factor-α, an immune system modulator. Some structural analogs of thalidomide are more effective than thalidomide itself.

Several anesthetics are chiral; this is the case for the inhalation anesthetics halothane, enflurane, and isoflurane, all used as racemates. Some work on isoflurane indicated enantiomer effects on pond snail nerve channels, where the (*S*) enantiomer (Fig. 16a) was twice as active as the (*R*) form in triggering an anesthetic-activated potassium current. In mice and rats, inhalation experiments with isoflurane enantiomers indicated a greater effect of the (*S*) form, but there were also contradictory results. It is likely that any enantiomer-selective effects for volatile anesthetics will be relatively weak.

More definitive results have been observed with intravenous anesthetics. One material, etomidate, is actually used as the single (*R*)-(+) enantiomer (Fig. 16b).

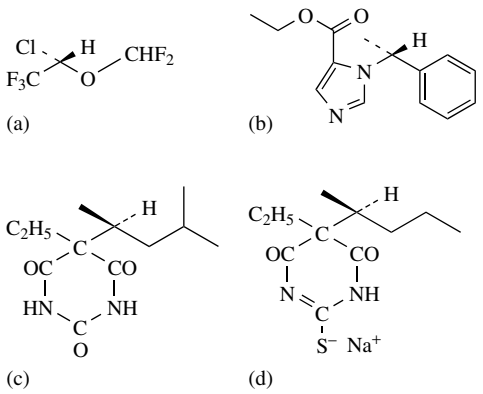

Fig. 16 Chiral anesthetic agents. (a) = (*S*)-isoflurane; (b) = (*R*)-etomidate; (c) = (*S*)-5-ethyl-5(1,3-dimethylbutyryl)-barbital; (d) = (*S*)-thiopental.

It is about five times as active as the (*S*)-(−) form. For the barbiturate compounds used as anesthetics and hypnotics, many agents show Case 3 pharmacodynamic action; a depressant activity is observed in the (*S*) forms, while an excitatory activity is associated with the (*R*) enantiomer. Thus, for 5-ethyl-5(1,3-dimethylbutyryl)-barbital, the (*S*) form (Fig. 16c) is a depressant and the (*R*) form is a convulsant; the racemate is also a convulsant and is not suitable for clinical use. In the clinically useful thiopental sodium, studies in mice and human volunteers indicate greater potency for the (*S*) form (Fig. 16d). However, in animals it yields a lower therapeutic ratio. It has a shorter terminal half-life being cleared and metabolizes more rapidly.

Drug enantiomers show many pharmacokinetic differences such as rates of adsorption and/or transport to receptor sites and in rates of metabolism to various end products. For more details, the specialist literature should be consulted. Further complications such as differences in animals versus humans and differences depending on sex and genetic makeup can arise.

One consequence of the interest in chiral drugs has been a lot of work of a chemical nature – for instance, the June 10, 2002 issue of *Chemical and Engineering News* features ''Chiral Chemistry'' as a cover story. Syntheses of chiral materials have been devised using asymmetric chemical catalysis, or enzymes, or microbial systems. Moreover, many chromatographic techniques have been developed for chiral separations, both analytically and for preparative purposes. This work is beyond the scope of this review.

4 Chiral Recognition

Enantiospecific physiological effects imply that enzymes or drug receptors achieve ''chiral recognition''. Much work has focused on the Easson–Stedman three-point attachment model, proposed initially to account for drug enantioselectivity. Given three specific binding sites in a plane, only one enantiomer can bind to the surface (Fig. 17). However, it is now clear that in the absence of specific constraints, the minimal requirement for chiral recognition is interaction between eight atomic centers, involving four different nonplanar centers on each interacting molecule. The interactions may

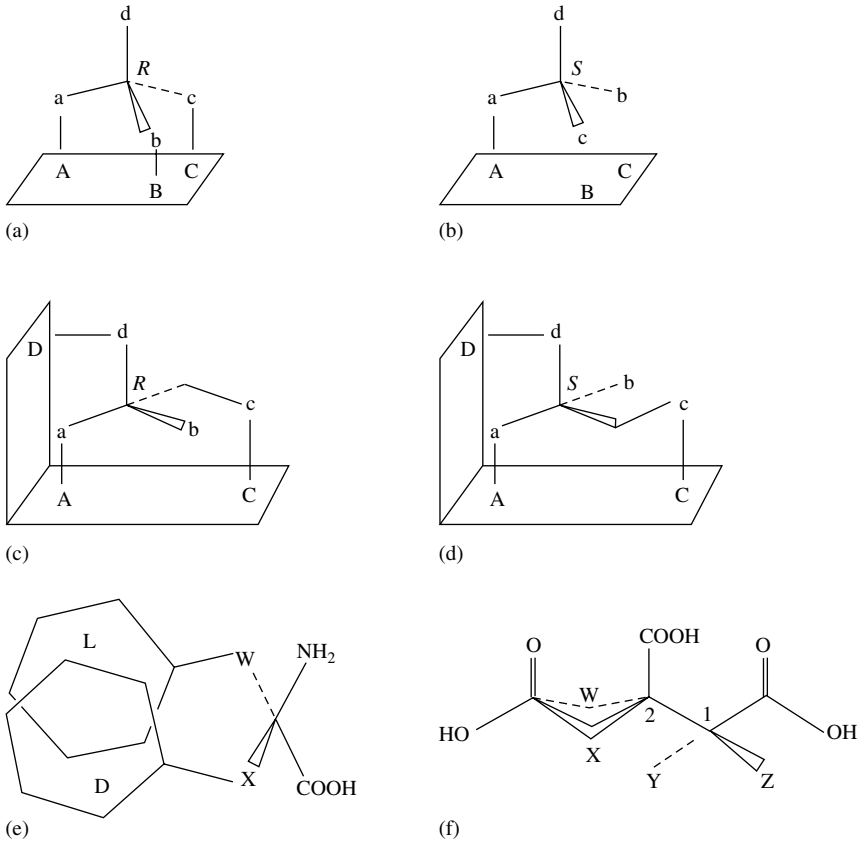

Fig. 17 Models for chiral recognition. (a), (b) show the conventional Easson–Stedman model for Cabcd (sequence assumed to be a > b > c > d). Three binding sites, A, B, and C, are in a plane and it is assumed that the substrate (drug) cannot approach from below (interior). Only the (*R*) enantiomer binds at all three sites, (a). (c), (d) diagram a modified model with three binding sites, A, C, and D, in three dimensions. The substrate (drug) is Cab(-CH_2-c)d. Under these circumstances, both (*R*) and (*S*) enantiomers can bind at three sites, (c), (d). A representation of mirror-image packing for phenylalanine enantiomers is drawn at (e). For D-phenylalanine, W = H, X = CH_2; for L-phenylalanine, W = CH_2, X = H. The aromatic rings (double bonds omitted) are drawn in the plane of the paper with NH_2 above and COOH below this plane. (f), Representation of mirror-image packing for isocitrate enantiomers. For (1*R*,2*S*)-isocitrate, W = CH_2, X = H, Y = OH, and Z = H. For the (1*S*,2*R*) enantiomer, W = H, X = CH_2, Y = H, and Z = OH. For both phenylalanine and isocitrate, the CH_2 group provides a flexibility that makes the mirror-image packing possible.

be either attractive or repulsive. In other words, the minimal requirement is for a four contact-point (four-point attachment) model. In the Easson–Stedman model, it was implicitly assumed that the drug or enzyme substrate could approach the protein surface only from above and not from below, that is, from the ''interior'' of the protein. Hence, this was a special case of the four-point attachment model. There

is a specific constraint (fourth condition) involved in the interaction.

In enzyme–substrate or drug–receptor interaction, there must be a diastereoisomeric relationship at some point in the pathway or in an intermediate compound/complex. If a chiral enzyme is denoted as (−E) and two substrate enantiomers as (+S) and (−S), the complexes (−E)(+S) and (−E)(−S) will be diastereoisomeric. Since diastereoisomers (unlike enantiomers) have different chemical properties, differentiation between (+S) and (−S) will, in principle, be possible. The occurrence of diastereoisomeric geometries is a necessary but not sufficient condition for chiral recognition.

In the reaction of phenylalanine ammonia lyase, both phenylalanine and substrate analog enantiomers bound to the enzyme; it was proposed that they occupied the same site with ''mirror-image packing.'' This possibility has been confirmed for isocitrate enantiomers in reaction with isocitrate dehydrogenase. These appear to be special situations deriving from the specific structures of the enzyme substrates (see Fig. 17). If three contact points are involved in mirror-image packing, clearly a fourth condition or site must be involved for chiral recognition as noted previously.

5 Enzyme Specificity with Chiral Substrates

Enzymes are polymers of many chiral amino acids. Thus, the relatively small enzyme, ribonuclease ($M_r = 13\,700$), has 109 amino acid residues with a single chiral center, 12 with 2 chiral centers and 3 residues of achiral glycine. Put in simple terms, this and other enzymes are highly chiral catalysts. Many texts contain statements such as the following actual example: ''It has long been known that natural enzymes act only on one chiral form (enantiomer) of a chiral substrate.'' While in general enzymes are often highly specific for one enantiomer, there are also many documented cases where specificity is not observed or is not absolute. An extensive listing of various situations and reaction types was given previously and only a few examples will be noted here.

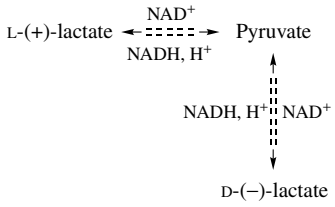
One highly specific case is D-amino acid oxidase (EC 1.4.3.3). Although L-amino acids are not substrates, several inhibit the oxidation of D-alanine (but not L-alanine). Presumably, these inhibitors bind at the normal active site. The amino acyl-tRNA ligases (synthetases, EC 6.1.1.X) apparently show absolute specificity for L-amino acids during ribosomal protein synthesis. These enzymes are of interest since they ligate two chiral substrates. When examined *in vitro*, there is some relaxation of the specificity as noted earlier for tyrosine-$tRNA^{tyr}$ ligase (EC 6.1.1.1). For arginine and proline ligases (EC 6.1.1.19 and EC 6.1.1.15 respectively), the D-enantiomers are inhibitory.

Examples of enzymes with lack of enantiospecificity are alcohol dehydrogenase (EC 1.1.1.1), where the liver enzyme reacts with both enantiomeric forms of butan-2-ol and octan-2-ol (although there are rate differences), and with nicotine dehydrogenase (EC 1.5.99.4), converting both nicotine enantiomers to the (*R*)- and (*S*)-6-hydroxynicotines. Further metabolism of the 6-hydroxynicotine enantiomers requires separate (*R*)- and (*S*)-6-hydroxynicotine oxidases (EC 1.1.3.6 and EC 1.5.3.5 respectively).

A remarkable achievement was the 1992 chemical synthesis of both enantiomeric forms of the dimeric enzyme HIV-1 protease; aminobutyrate was an isosteric replacement for cysteine at monomer

positions 67 and 95. The all-D and all-L proteins were in every respect mirror images, apart from enzymatic activity. They were enantiospecific in cleavage of a hexapeptide analog of a normal cleavage site. The all-D analog 2-aminobenzoyl-D-thr-D-ile-D-nle-D-*p*-nitrophe-D-gln-D-arg($CONH_2$) was cleaved only by D-enzyme; conversely, the L-enzyme cleaved only the all-L hexapeptide (nle = norleucine).

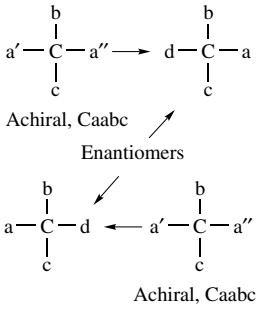
In several cases, there are separate enzymes for enantiomeric substrates; examples include D- and L-amino acid oxidases, D- and L-lactate dehydrogenases, D- and L-arabinose 1-dehydrogenases, and the two 6-hydroxynicotine oxidases previously noted. Such enzymes acting in concert would provide a racemase possibility, for example, for lactate dehydrogenases:



In other cases, a single enzyme functions as a racemase and is, therefore, an example of an enzyme utilizing both enantiomers. Racemase enzymes are especially well known for amino acids (e.g. serine racemase noted earlier) and hydroxyacids (e.g. lactate, mandelate). An important enzyme involved in propionyl-CoA metabolism interconverts the (*R*) and (*S*) forms of methylmalonyl-CoA (Fig. 18). Although often termed *methylmalonyl-CoA racemase*, this enzyme is technically not a racemase since the five chiral centers of the CoA component are (presumably) unchanged. The more appropriate name is methylmalonyl-CoA epimerase (EC 5.1.99.1).

6 Prostereoisomerism

Many enzyme substrates have the general achiral structure, Caabc; there are two chemically like atoms or groups of atoms, a, and two different atoms or groups of atoms, b and c. Although these structures are achiral, the two a groups are in different stereochemical environments. For convenience, the a groups will be distinguished as a′ and a″. When a′ is observed as if to determine chirality by the Cahn–Ingold–Prelog method, the sequence a″ → b → c has a right-handed sense (Fig. 19a). Similarly, with a″ in the remote position, the sequence a′ → b → c has a left-handed sense (Fig. 19b). If each a group is imagined to be replaced by a further group, d, the two enantiomers of a chiral compound, Cabcd, are obtained (see below).



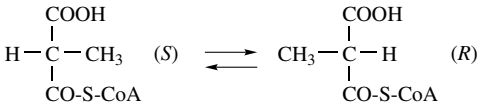


Fig. 18 Methylmalonyl-CoA epimerase. The chiral centers in the CoA unit do not undergo inversion during the epimerization.

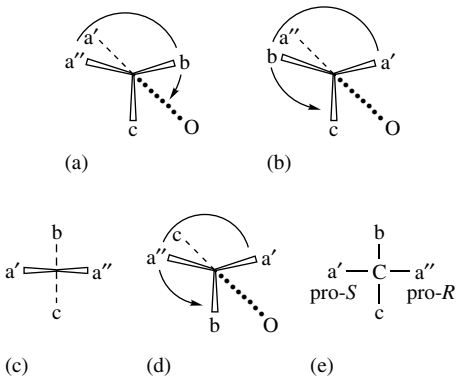

Fig. 19 Prochirality in Ca′a″bc. The different stereoisomeric environments for a′ and a″ are shown as (a) and (b). (c) = conventional three-dimensional representation of cCa′a″bc. (d) = prochirality determination if the sequence is a′ > a″ > b > c; O = eye of observer. The sequence, a′ → a″ → b, is left-handed, hence the promoted group, a′, is pro-*S*. (e) = final arrangement.

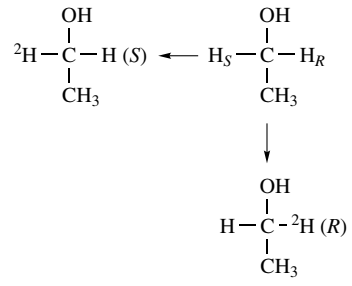
For that reason, Caabc is often described as a prochiral structure; it is preferable, however, to refer to the situation as prostereoisomerism.

A chiral reagent, usually an enzyme, is able to differentiate between a′ and a″ in Ca′a″bc. This possibility was rationalized by Ogston in terms of a three-point attachment model exactly as for chiral recognition (at the time of his suggestion, Ogston was unaware of the Easson–Stedman model). It is now apparent that the three-point attachment model is a special case and that in the absence of specific constraints (e.g. substrate cannot approach from the interior of the protein), eight center interactions are required – a four-location model.

Stereochemical descriptors for prostereoisomeric ligands derive from an extension of the Cahn–Ingold–Prelog system. One a group, say a′, is arbitrarily assigned a higher priority in the sequence rule than the other, a″. If the "normal" sequence for Caabc is a > b > c, the "modified" sequence becomes a′ > a″ > b > c. The model is then viewed in the usual way from the side remote from the lowest priority group, c. If the sequence, a′ → a″ → b is right-handed, the "promoted" group a′ is assigned the pro-*R* descriptor and a″ is assigned the pro-*S* descriptor (Fig. 19c–e). The descriptors can also be obtained from projection models, as described previously for chiral centers. If the two a groups are hydrogen atoms, the descriptors are written as H_R and H_S. A specific case concerns the two CH_2-COOH groups of citric acid; the modified sequence is OH > COOH > $C'H_2-C'OOH$ > $C''H_2-C''OOH$ and the descriptors are derived as shown in Fig. 20. Moreover, in citric acid, each CH_2 group contains H_R and H_S possibilities. In the important aconitase reaction, it is H_R of the pro-*R* methylene group that is removed along with OH in the formation of *cis*-aconitate (Fig. 20).

Replacement of H_R and H_S, for example, in CH_3-CH_2-OH, by ^2H leads to the two enantiomers of [1-^{2}H]-ethanol; optical activity has been demonstrated for



the enantiomers; (*S*) is (−) and (*R*) is (+).

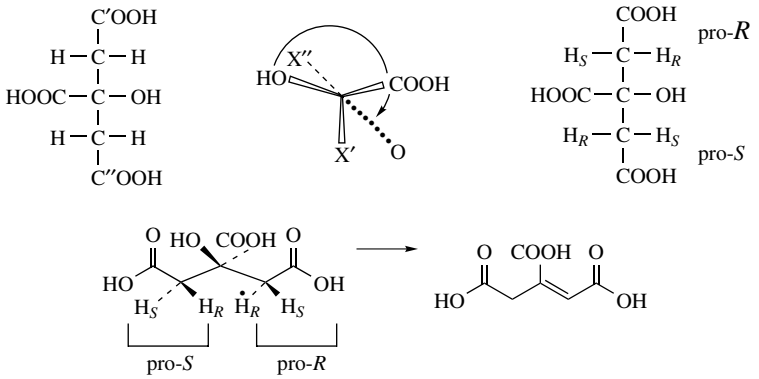


Fig. 20 Prochirality considerations for citric acid. The three structures at the top show the assignments for the CH_2COOH groups and the hydrogens of the CH_2 groups; X′ = $CH_2C'OOH$, X″ = $CH_2C''OOH$; O = eye of observer. The "promoted" priority sequence is HO > COOH > $CH_2C'OOH$ > CH_2 C″OOH. Derivations for H_R and H_S are not shown. The bottom line shows the action of aconitase (citrate → H_2O + *cis*-aconitate) The H_R proton (identified as •) is removed from the pro-*R* methylene group.

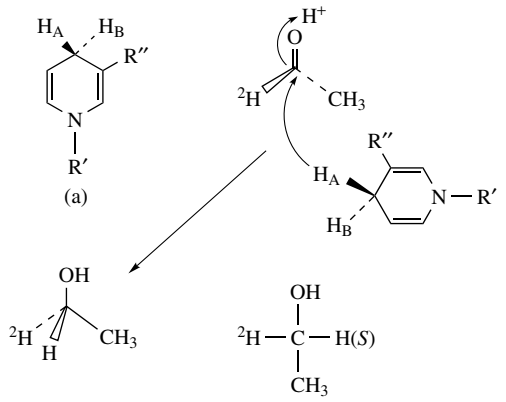
Fig. 21 Alcohol dehydrogenase stereochemistry. (a) = the reducing cofactor, NADPH; R^1 = rest of structure, R^2 = $CONH_2$. The H_A (=H_R) hydrogen is transferred to form (*S*)-[2-^{2}H]-ethanol.



The "faces" or "sides" of trigonal carbon atoms can also be distinguished. For instance, the enzymatic reduction of [1-^{2}H]-acetaldehyde is stereospecific with respect to the face of the carbonyl group (Fig. 21). If the enzyme used is alcohol dehydrogenase, there is a further factor – the two hydrogens at C-4 of the reducing coenzyme, NADH, are prostereoisomeric. They are often described as H_A and H_B, corresponding respectively to H_R and H_S. For citrate synthase, catalyzing the formation of citrate from oxaloacetate and acetyl-CoA, the "incoming" CH_2COOH unit, derived from acetyl-CoA, occupies the pro-*S* position in citrate – the carbonyl of oxaloacetate was attacked from only one side (Fig. 22). Stereochemical descriptors to define the sides and faces of trigonal carbon atoms have been devised; the specialist literature should be consulted.

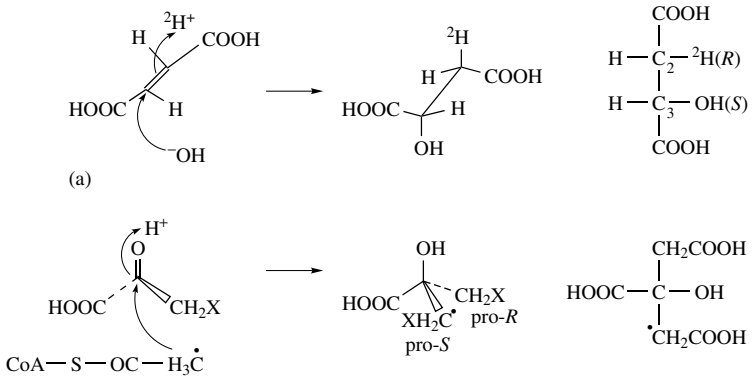


Fig. 22 The fumarase and citrate synthase reactions. (a) The top line shows fumarase addition of ^2H_2O to fumarate leading to production of (2*R*,3*S*)-[2-^{2}H]malate. (b) The lower line shows the addition of acetyl-CoA to oxaloacetate; X = COOH. Use of ^{13}C-labeled acetyl-CoA (^{13}C identified as •) yields ^{13}C in the pro-*S* position of citrate.

Similar considerations apply to addition reactions at double bonds, C=C. Thus, in the action of fumarase on fumarate in ^2H_2O, the OH group attacks from below the double-bond plane and H^+ enters from above the plane, thus leading to formation of (2*S*,3*R*)-[3-^{2}H]-malic acid (Fig. 22).

Since ^{2}H is readily available at 100% concentration, $^2H-CH_2-COOH$ can be prepared. In this compound, the two ^{1}H atoms are in a prostereoisomeric relationship. If a further substitution of one ^{1}H by 100% ^{3}H were practicable, a chiral compound would be formed, [^{3}H,^{2}H,^{1}H]-acetate, and theoretically optical activity would be observable. Because of the very high level of radioactivity associated with 100% ^{3}H, it is unlikely that this statement will be put to the proof. However, normal tracer levels of ^{3}H can be used to explore the chirality of methyl groups containing all three of the hydrogen isotopes. The two enantiomeric acetates (Fig. 23a, b) can be synthesized either chemically or by combined enzymatic and chemical methods; their chirality is demonstrated as follows. The acetate samples are converted to the CoA derivatives and the latter are used as substrates in the malate synthase reaction (EC 4.1.3.2; glyoxylate + acetyl-CoA → L-(*S*)-malate). In this reaction, a marked isotope effect dictates removal of ^{1}H in preference to either ^{2}H or ^{3}H. In turn, the malate samples are treated with fumarase (EC 4.2.1.2, fumarate hydratase, L-(*S*)-malate → H_2O + fumarate) and the fumarate is examined for ^{3}H radioactivity (Fig. 23).

The overall result is that from (*R*)-[^{1}H,^{2}H,^{3}H]-) acetate, ^{3}H is predominantly retained in the isolated fumarate (ca. 80% retention) and from the (*S*) enantiomer, ^{3}H is predominantly lost (ca. 20% retention). While loss/retention of ^{3}H is not 100%, such completeness is not expected; the actual value depends on the nature of the isotope effect in the malate synthase reaction. This malate synthase/fumarase system demonstrates the chirality of the methyl group and provides a convenient assay method for the chirality of acetate

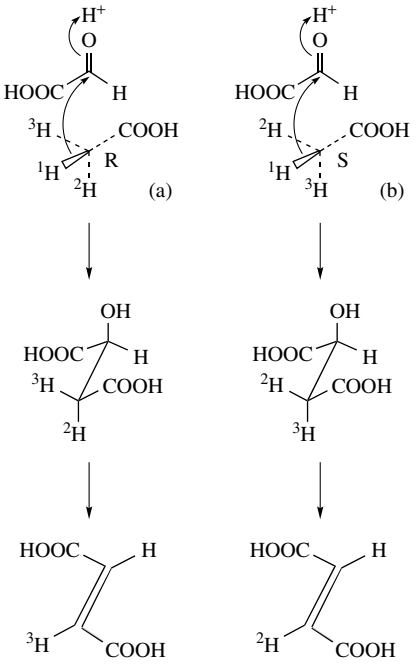

Fig. 23 Analysis of chiral acetates. The first reaction is that of malate synthase, glyoxylate + acetyl-CoA → malate (for simplicity, the samples are shown as acetate rather than as acetyl-CoA). An isotope effect dictates removal of ^{1}H as shown. The second reaction is that catalyzed by fumarase – removal of the elements of water with defined *trans* stereochemistry. The possible fumarate products are shown on the last line.

samples. There have been many investigations of chiral methyl groups in biochemical processes.

In a similar way, chiral phosphates, containing ^{16}O, ^{17}O, and ^{18}O, and chiral phosphorothioates, containing S, ^{16}O, and ^{18}O, have been utilized in several enzymatic reactions. Thus, in the action of adenylate kinase, a phosphorothioate analog of ATP was used to show that the reaction proceeds with overall inversion of configuration (Fig. 24). Similarly, with the use of all three of the oxygen isotopes, glucose phosphorylation by hexokinase was also shown to proceed with inversion of configuration.

7
Chirality in Biological Structures and Behavior

7.1
Structures

Chirality occurs in many manufactured objects (e.g. screws, propellers, shoes) and is very common in the world of nature. When viewed externally, the bodies of humans and most animals show an overall bilateral symmetry. A mirror plane can be imagined at right angles to the body, thus bisecting the nose and legs. Usually, this symmetry is imperfect with slight differences say between the left and the right hands (the right hands of right-handed people are usually larger than the left hands). Irregularities are often seen in faces. Faces artificially constructed from two left or two right sides are markedly

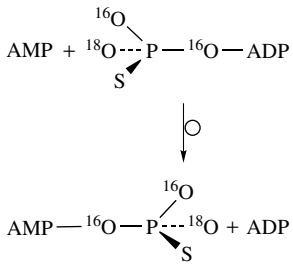

Fig. 24 The mechanism of action of adenylate kinase, EC 2.7.4.3. The catalyzed reaction is ATP + AMP = ADP + ADP. ATP is shown as a phosphorothioate analog containing ^{16}O, ^{18}O, and S (double bonds are omitted). The ''looped arrow'' indicates that the reaction involves inversion of configuration at the phosphorous atom.

different from the original. Faces on some statues are actually mirror symmetric and have been described as having an ''eerie beauty.''

The internal arrangement of body organs, however, lacks symmetry. As the embryo develops, the heart, spleen, and stomach normally assume the left side of the chest cavity, while the major lobe of the liver and the gall bladder locate on the right side of the abdomen. The left lung usually has two lobes, the right, three. In the condition of *situs inversus*, there is a transposition of the viscera, the liver being on the left, the heart on the right. This condition occurs with a frequency of 1 per 10 000 births. It seems surprising that individuals with *situs inversus* generally are right-handed. Of 160 cases of *situs inversus* in which handedness was known, only 11 were left-handed.

A rarer situation is that of individuals who are much more symmetrical than normal. In ''right isomerism,'' both lungs have three lobes, the heart has two right atrial appendages, the liver is central, and the spleen is absent. For a male patient, the testicles are of the same length (the right testicle is usually longer). In ''left isomerism,'' the lungs are two-lobed, the heart has two left atrial appendages, the liver is central, and the individual possesses multiple spleens. Individuals with either isomerism have serious problems with heart function.

Mutant mice showing *situs inversus* are known. The *iv* mutation (*inversus viscerum*) gives about 50% of cases of *situs inversus*. The different *inv* mutation (abbreviation of ''inversion of embryonic turning'') yields 100% inversion; these mice die early in life.

Of the primary axes of the embryo (anterioposterior, dorsoventral, and left/right asymmetry), much attention has been focused on the left/right asymmetry axis in recent years. Answers are being sought, primarily at the genetic level, to questions about what determines the asymmetry and how does it develop. Several genes or gene clusters have been identified, but there still is relatively little information about the gene products. The subject is too complex for discussion here.

There are many exceptions to overall bilateral symmetry; only a few examples can be given. Lobsters have one small limb for clutching and a large one for tearing. In 50% of the population, the small limb is on the left and in the other 50% it is on the right. Similarly, in male fiddler crabs the large claw or pincer is to the left in 50% of the population and to the right in the other 50%. In male narwhals, a large ivory tusk (up to 10 feet long) pierces the upper lip on the left side of the body and shows a striated spiral pattern from right to left. In birds, the New Zealand wry-billed plover has a beak that is always bent to the right-hand side of the bird. Similarly, a breed of European finches, termed *crossbills*, has an upper mandible pointing to the bird's right and the lower to the left. This crossed arrangement may facilitate removal of a seed from a pinecone directly with the mouth. North American crossbills have the opposite asymmetry. Clearly, the arrangement provides some advantage, whatever direction it takes.

Chirality is well illustrated in mollusk shells. In most cases, the helical direction is right-handed, but some whelks (e.g. the Florida lightning whelk) are left-handed. Rare examples of ''sinistral,'' left-handed shells, for normally right-handed types, are prized by collectors. In India, the left-handed form of the chank shell (*Turbinella pyrum*) is considered sacred by Hindus. Very ancient statues portray

the god, Vishnu, as holding a left-handed chank shell

In tobacco plants, leaves alternate along the stem in either a left-handed or a right-handed spiral. In large populations, the left : right ratio is 1 : 1. Vining plants coil upward in a left- or right-handed spiral characteristic of the species; honeysuckle is right-handed and bindweed is left-handed.

Even microorganisms can show chiral growth patterns. In *B. subtilis*, one structural possibility consists of filaments of many individual cells with a double-stranded helical arrangement. The helix chirality and degree of twist are influenced by growth conditions. There is a range from ''maximum tight left-handedness'' to ''maximum tight right-handedness.'' Some mutants have only one helical chiral sense. In a truly bizarre case, one fungal species of the genus *Laboulbenia* parasitizes beetles. It occurs only on a single joint of the left hind leg; no other part, including the right leg, is involved.

7.2 Behavioral Asymmetries

That the two parts of the brain have different functions became apparent from studies of brain-damaged individuals. Early work was carried out in France by Marc Dax, with more extensive studies by Pierre Paul Broca (1824–1880), a surgeon. Broca determined that language facility and action are usually associated with the left hemisphere of the brain – in his words (1865), ''On parle avec l'hémisphère gauche.'' In the condition of Broca's aphasia (or motor aphasia), the power of expression by writing, speaking, or signs is lost. In 1995, another form of mental performance, perfect pitch, was attributed to the left brain. Still more recently, left-hemisphere cerebral specialization was reported for the babbling of babies, either those acquiring English or those acquiring French. The right hemisphere is involved with processes of perception. Hence, right-brain damage involves not only sight but also other senses such as touch, sound, and taste. Much has been written on the left-brain/right-brain situation and specialized texts should be consulted for further details. The situation is complex and there are exceptions to the generalizations just noted.

Perhaps even more complex is the subject of handedness; again, much has been, and continues to be, written on this subject. In the Western nations, a little over 10% of the population is left-handed (defined as those using the left hand for at least half of their tasks). Left-handedness is more common among women than men, and individuals can be inconsistent in their hand usage. Similar preferences exist for the use of feet, eyes, and ears. There has been much speculation concerning the origin of handedness. A genetic component is probably involved and left-handedness in humans (but not in animals) runs in families. Studies of twins have posed some problems for genetic hypotheses. For instance, with identical twins, about one in five pairs shows nonidentical handedness, one twin being right-handed, the other, left-handed.

There are two genetic models, one proposed by Annett, the other by McManus. In brief, Annett postulates a gene, *RS+*, that displaces the chance distribution to the right (the right-shift model), whereas McManus postulates two alleles, *D (Dextral)* and *C (Chance)*, at a single autosomal locus. The *DD* genotype produces exclusively right-handed individuals, while the

CC genotype results in ''fluctuating asymmetry,'' that is, a 1 : 1 distribution. The *DC* genotype yields 25% left-handedness. The original hypotheses have been modified and subject to criticism and the topic cannot be summarized simply. It is noteworthy that in a 1991 Symposium, ''Biological Asymmetry and Handedness,'' a paper by McManus (The Inheritance of Left-handedness) was extensively discussed by the participants. The recorded comments comprise about 7000 words. The genetics of left/right asymmetry in bodily organs are under study, but apparently none of the identified genes have been implicated in behavior.

8 Origin of Chirality on Earth

Many attempts to explain the emergence of life on planet Earth and the establishment of homochirality for the major macromolecules, nucleic acids, proteins, and carbohydrates have led to little agreement. One difficulty is that experimental chemical approaches to prebiotic conditions produce racemic compounds if a chiral center is involved. Two general possibilities are (1) that the first significant molecules for evolution of life were already formed with one chiral sense in place or (2) that initially produced racemic mixtures were subjected to chiral enrichment by a selection process.

Actual mechanisms under consideration are legion-interactions with polarized β-radiation from nuclear decay, interactions with circularly polarized light, selective adsorption, or polymerization on crystals or clays, stochastic sorting of conglomerate crystals, enantioselective magnetochiral photochemistry, stirring, and chiroselective amplification. A recent development is the suggestion that life may have arisen in high-temperature environments with prebiotic synthesis in an environment of iron sulfide and hot magmatic exhalations.

Another general suggestion is that extraterrestrial organic compounds may have been transported to Earth and used for evolutionary processes. Certain amino acids are definitely present in meteorites, most famously, the Murchison. There has been some evidence concerning possible enantiomeric excess in such amino acids, particularly those that do not occur in proteins. There are, however, conflicting reports, and the possible contamination of meteorite material by terrestrial material is real. To overcome such difficulties, instrumental approaches to detecting chirality in, for example, amino acids, are being prepared for space missions to Mars and comets.

Another major area of discussion relates to the possibility that earthly homochirality reflects the fundamental structure of matter itself, in particular, the nonconservation of parity with the weak force as carried by W^+ and Z^o particles. The weak force is the only one that is chiral. The universe has an intrinsic ''left-handedness'' – it is made of matter and not antimatter, and the parity-violating differences between enantiomers might determine biomolecular chirality. The handedness of particles implies that L and D molecules are actually diastereoisomers; the true enantiomer of, say, L-alanine would be D-alanine made from antimatter. Some authors believe that the possible selectivity in such processes is too small and yet others view the initial choice as a random event.

For life as we know it, all D-proteins and nucleic acids with L-ribose and L-deoxyribose would (presumably) have been equally acceptable – this point of view is bolstered by the work previously described with all-D HIV protease. Perhaps

somewhere in the Universe there is, indeed, a ''looking-glass'' world in which Alice would find that looking-glass milk containing lactose, with L-glucose and L-galactose components, was good to drink.

Keywords

BAC
Bacterial artificial chromosome, large cloned segment of chromosomal DNA that can be propagated in bacteria.

Cosmid
A plasmid that contains phage lambda cos sites and therefore can be packaged *in vitro* into phage coats.

DNA Complexity
The total length of different DNA sequences contained within a given DNA preparation; the DNA complexity is usually given in kilobase pairs (kb; 1 kb = 1000 base pairs).

EST
Expressed sequence tag, sequence of gene fragment obtained by high-throughput sequencing.

Intron
A segment of DNA within a gene that is transcribed but removed from the RNA transcript by splicing together the flanking coding sequences (exons).

Linkage Group
All loci that are linked together by genetic criteria, as an entity, and correspond to a chromosome.

Open Reading Frame
A DNA sequence that consists of a series of triplets (codons) coding for amino acids and potentially encodes a protein.

Splicing
Process of removing introns from a precursor RNA and joining of flanking exons.

The highly diversified, polyphyletic genus Chlamydomonas comprises more than 450 species of unicellular flagellated photosynthetic algae. These organisms are especially attractive for several areas of research in cell and molecular biology because of their small size, fast growth rate, and short sexual cycle. However, only a few species have been actively used for molecular genetic studies. They include the heterothallic species *C. reinhardtii* and *C. smithii*, which are in the line of descent leading to the multicellular species *Volvox*; the sibling species pair *C. eugametos* and *C. moewusii*, both very distinct from *C. reinhardtii*; and the homothallic species *C. monoica*. This article focuses on *C. reinhardtii* because this alga has emerged as the organism of choice for most investigations. *Chlamydomonas eugametos* and *C. moewusii* have also

been used for studies on mating and chloroplast inheritance. However, since in contrast to *C. reinhardtii* both these species are obligate photoautotrophs, their use is more limited. *Chlamydomonas monoica* is particularly suited for the analysis of the genetic control of sexuality, and several mutants defective in mating-type or zygote formation have been isolated and characterized.

Major technical advances have been achieved recently with *C. reinhardtii*. They include the development of reliable transformation methods for the nuclear, chloroplast, and mitochondrial compartments. Gene tagging and nuclear gene rescue of mutants with genomic libraries are also feasible. *Chlamydomonas* genomics projects have created large sets of ESTs that have greatly facilitated the cloning of nuclear genes of known function, and the *Chlamydomonas* nuclear genome sequence has been determined recently.

With these new tools, *C. reinhardtii* has become a powerful model system in which it is possible to perform an extensive molecular genetic dissection of fundamental biological processes, in particular photosynthesis, organellar biogenesis, and flagellar function and assembly.

1 The Organism

The characteristic features of *C. reinhardtii* are its unique cup-shaped chloroplast, which occupies nearly half of the cell volume, and its two flagella (Fig. 1). In this organism, photosynthetic function is dispensable, provided a reduced carbon source such as acetate is included in the growth medium. The alga can, therefore, be grown under three different regimes: phototrophic growth with CO_2 assimilated through photosynthesis as the unique carbon source, heterotrophic growth in the dark with acetate, and mixotrophic growth in the light with acetate. These growth properties have been used extensively to isolate and maintain numerous mutants deficient in photosynthetic activity. The cell division cycle of this alga can also be synchronized by subjecting cells to alternate light and dark cycles.

Haploid vegetative cells of *C. reinhardtii* exist as mating-type$^+$ or mating-type$^-$, determined by alternative alleles of a nuclear gene, and can be propagated indefinitely through mitotic divisions (Fig. 2). Gametogenesis is usually induced when vegetative cells are starved for nitrogen. Gametes formed from synchronously grown *C. reinhardtii* display several characteristic features such as loss of ribosomes, alterations of chloroplast morphology, starch accumulation, and reduced photosynthetic activity. The mixing of gametes of opposite mating type is followed by a rapid adhesion of their flagella. Since an individual gamete can adhere to more than one cell of opposite mating type, clumps of gametes are formed. This response appears to be mediated through gamete-specific glycoproteins called *agglutinins*, which are associated with the flagellar membrane and can be released as vesicles from the flagellar tips. This agglutination triggers flagellar-tip activation, loss of cell walls, and activation of mating structures, in which specialized regions differentiated at the cell anterior

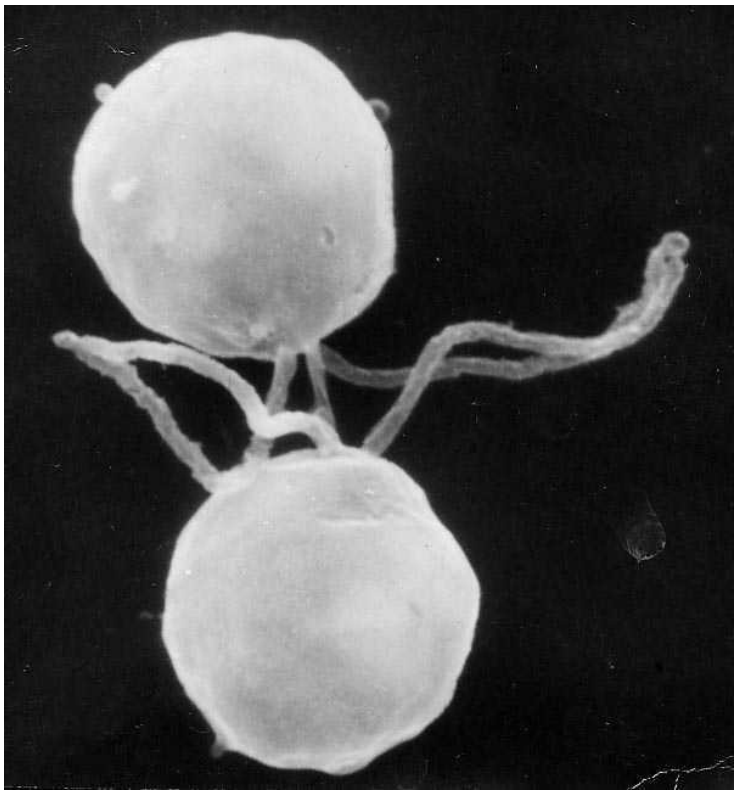

Fig. 1 Scanning electron micrograph of two *C. reinhardtii* gametes of opposite mating-type during the initial stage of mating (Courtesy of U. Goodenough).

give rise to the fertilization tube of the mating-type^{+} cell. This series of complex reactions ultimately leads to the fusion of gametes and, subsequently, of their nuclei and chloroplasts. The resulting zygote matures into a thick-walled zygospore, which can be induced to undergo meiosis and produce a tetrad consisting of four haploid spores. Vegetative diploids can also be selected from matings or poly(ethylene glycol)-mediated cell fusions. They divide mitotically and allow one to determine whether a mutation is dominant or recessive. Vegetative diploids have also proven to be useful for isolating chloroplast and mitochondrial mutations affecting photosynthesis and respiration respectively. The most frequent mutations of this type are nuclear and recessive and, therefore, are not expressed in diploid cells, whereas chloroplast and mitochondrial mutations will segregate to yield mutant isolates.

Recently established methods of cytoduction allow the transfer of chloroplast or mitochondrial markers into a defined nuclear genetic background in *C. reinhardtii*. In this process, fusion of cytoplasms of the two parents occurs in the absence of nuclear fusion. This leads to the appearance of cytoductants containing the nuclear genome of one parent and cytoplasmic components of both parents. During further divisions, segregation occurs and the cytoplasmic marker of one

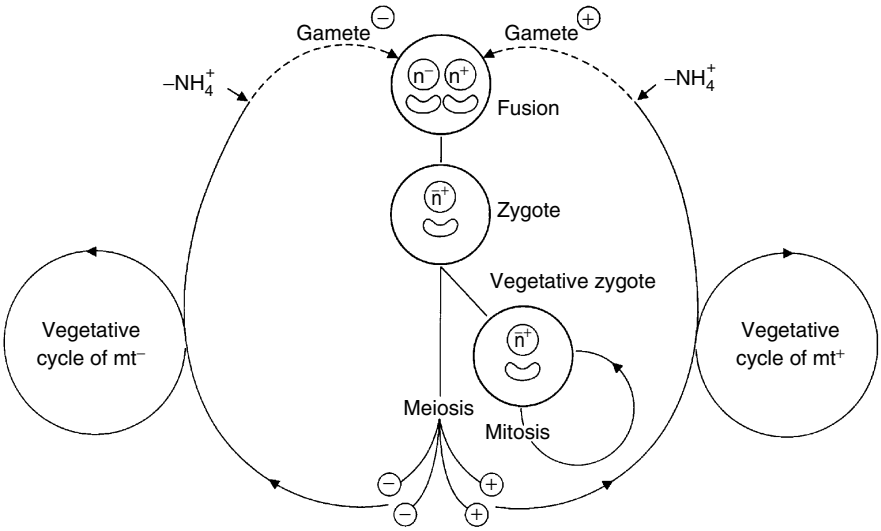

Fig. 2 Life cycle of *C. reinhardtii*: mt, mating-type; n, nucleus; the chloroplast is shown below the nucleus. See text for explanation. [Reproduced with permission from J.-D. Rochaix, FEMS *Microbiol. Rev*. **46**: 13–34 (1987).]

parent becomes associated with the nucleus from the other.

2 Three Autonomous Genetic Systems

Like higher plants, *Chlamydomonas* contains three genetic systems, located in the nucleocytosol, the chloroplast, and the mitochondria. In contrast to nuclear genes, which are transmitted to the offspring in a Mendelian fashion, chloroplast and mitochondrial DNAs are usually transmitted uniparentally from the mating-type$^+$ and mating-type$^-$ parent respectively. In *C. eugametos* and *C. moewusii*, both organellar genomes are transmitted uniparentally from the mating-type$^+$ parent (Table 1).

Tab. 1 Three genetic systems in *Chlamydomonas*.

System	*Species*	*Complexity of genome [kb]*	*Number of linkage groups*	*Copy number*	*Inheritance*
Nucleus	*reinhardtii*	10^5	17		Me
Chloroplast	*reinhardtii*	204	1	80	up$^+$
	eugametos	343	1		up$^+$
	moewusii	292	1		up$^+$
Mitochondria	*reinhardtii*	15.8	1	50	up$^-$
	eugametos	20.2	1		up$^+$
	moewusii	18.5	1		up$^+$

Notes: Me: Mendelian inheritance; up$^+$, up$^-$: uniparentally inherited from the mating-type$^+$ and mating-type$^-$ parent respectively.

2.1 Nuclear Genome

The complexity of the nuclear genome of *C. reinhardtii* has been estimated at 1×10^5 kb. At least 17 nuclear linkage groups have been identified with numerous markers (http://www.biology.duke.edu/chlamy_genome/nuclear_maps.html). These include auxotrophic mutations, drug-resistant markers, mutations affecting photosynthesis directly or indirectly, flagellar function, and mating. The use of restriction fragment length polymorphisms (RFLPs) to follow the segregation of specific DNA fragments in the genome has greatly accelerated genetic mapping. Efforts to establish RFLP maps for several of the nuclear linkage groups of *C. reinhardtii* are under way. A large collection of BAC clones covering the nuclear genome has been established and was used to sequence the entire genome. Telomere sequences from *C. reinhardtii* have been isolated and characterized. They are found at the chromosome ends with an average length of 300 to 350 bp, and they consist of the simple invariant repeat TTTTAGGG, which is very similar to its counterpart in *Arabidopsis thaliana*. Telomere-associated sequences, defined as the sequences close to the telomere repeats, appear to be useful markers for establishing RFLP maps.

Many nuclear genes of *C. reinhardtii* have been characterized. Genes that are highly expressed (e.g. those encoding proteins of the photosynthetic and flagellar apparatus or the heat shock proteins) display a strong codon bias. In general, cytidine (C) or guanine (G) residues at the third position of the codons are most common and, if possible, also in the first position, reflecting the high GC content (63%) of the nuclear DNA. However, genes that are less expressed, such as cytochrome c_6 and arylsulfatase, show a considerably more balanced codon usage. An A-rich sequence resembling the TATA box can usually be recognized in the upstream region of the nuclear genes of *C. reinhardtii* with an adjacent GC-rich stretch. In all the cases examined, a putative polyadenylation recognition motif TGTAA is found at the 3′ end, 10 to 15 nucleotides upstream of the polyadenylation site. Another distinctive feature of the nuclear genes of *C. reinhardtii* is the presence of multiple introns. As an example, the gene of one heat shock protein, hsp70, contains six introns, whereas its counterpart in plants contains only one intron, or none at all.

2.2 Chloroplast Genetic System

The chloroplast genome of *C. reinhardtii* has recently been sequenced and found to consist of 204 kb circular molecules. It is, therefore, larger than the plastid genomes of land plants, which range between 120 and 160 kb. Although the informational content of this DNA is low, about 0.2% of the cell DNA complexity, it constitutes 10 to 15% of the cellular DNA mass because it is present in approximately 80 copies per cell, which are arranged into 8 to 10 nucleoids within each chloroplast. The chloroplast DNA of *C. reinhardtii* is AT-rich and, therefore, its density differs considerably from that of nuclear DNA. This property can be used for purifying chloroplast DNA from total cell DNA by density gradient centrifugation. The striking differences in codon usage between nuclear genes and chloroplast genes suggest that these genomes are distinct in origin, in agreement with the endosymbiotic theory, according to which chloroplasts have evolved from photosynthetic prokaryotes that took up

an internal symbiotic relationship with the ancestor of eukaryotic plants and green algae. Other similarities between chloroplasts and photosynthetic bacteria supporting this theory are discussed in the paragraphs that follow.

Sequencing of the chloroplast genome of *C. reinhardtii* has revealed that it contains 99 genes. They include genes involved in photosynthesis, genes of the components of the chloroplast gene expression system, genes involved in posttranslational steps, and other genes of unknown function (Fig. 3, Table 2). Many of these genes are also found in the plastid genomes of higher and lower plants. Although the chloroplast genome of *C. reinhardtii* is larger than those of land plants, it has lost numerous coding regions that are still present in other chloroplast genomes. The large size of the chloroplast genome of *C. reinhardtii* is due to the presence of many

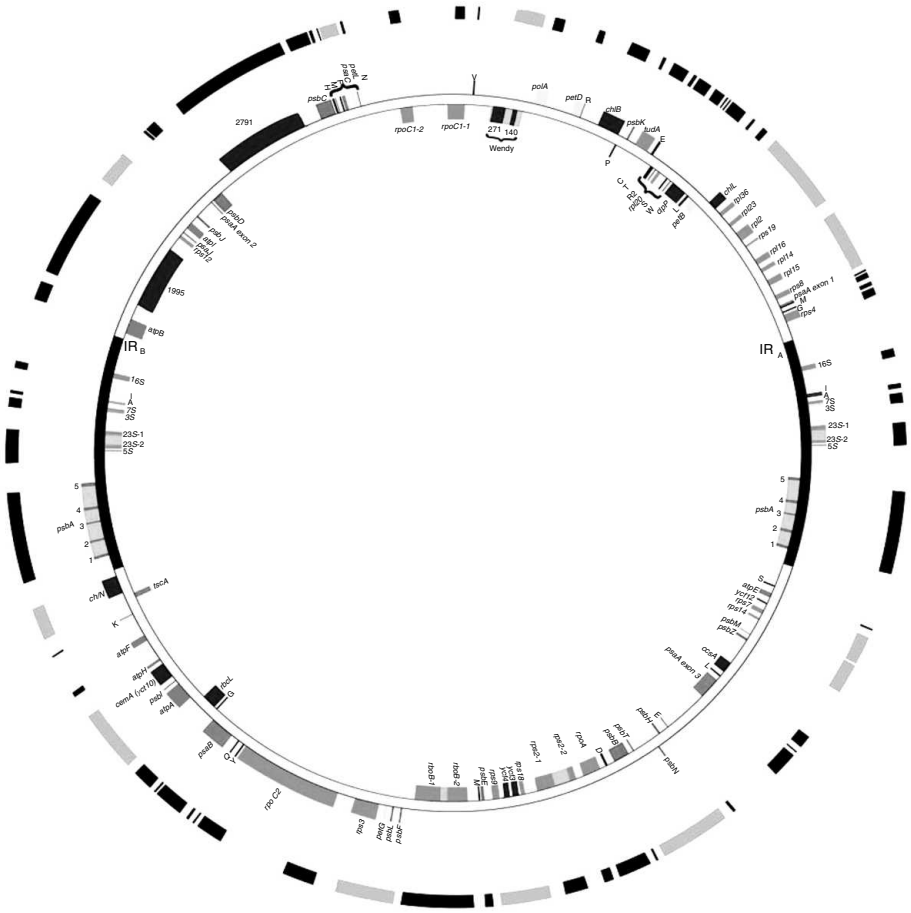

Fig. 3 Map of the chloroplast genome of *C. reinhardtii* with transcribed regions. See Table 2 for gene nomenclature. The outer circle indicates the transcribed regions: monocistronic RNAs (black), polycistronic RNAs (gray). [Reproduced with permission from Lilly et al. *Plant Cell* **14**, 2681–2708 (2002).]

[a]Genes containing introns.
The arrangement of these genes on the chloroplast genome of *C. reinhardtii* is indicated in Fig. 3.

short dispersed repeats that account for more than 20% of its sequence. Moreover, the chloroplast genes of *C. reinhardtii* are usually larger than their land plant counterparts. While the organization of these genes on the chloroplast genomes of plants has been conserved to a remarkable extent, this conservation does not extend to Chlamydomonas. Even among *C. reinhardtii, C. eugametos,* and *C. moewusii,* the arrangement of chloroplast genes is rather different. The rearrangements of the chloroplast genome appear to be correlated with, and probably mediated through, the short dispersed repeats.

Besides the numerous genes that are found in plants and Chlamydomonas, several chloroplast genes have been identified in algae that are not present in the chloroplast genomes from land plants.

The *tuf*A gene encoding EF-Tu is located in the chloroplast genome in *C. reinhardtii* and in the nuclear genome in all higher and lower plants examined. Three chloroplast genes encoding subunits of the enzyme involved in light-independent protochlorophyllide reduction are present in *C. reinhardtii* but not in higher plants. Interestingly, these genes are also present in the chloroplasts of lower plants and pines that, together with *C. reinhardtii*, are capable of synthesizing chlorophyll in the absence of light. Finally, a few open reading frames (ORFs) of unknown function and unique to *C. reinhardtii* have been identified. Chloroplast genes that are absent from *C. reinhardtii*, but present in land plants include those encoding several ribosomal proteins and subunits of the NADH dehydrogenase. This enzyme is thought to mediate electron transfer from reduced stromal components to the plastoquinone pool of the photosynthetic electron transfer chain.

The chloroplast DNA is associated with small basic proteins and appears to be under torsional stress. Both relaxing and supercoiling topoisomerases have been detected in the chloroplast, and inhibition of the latter with novobiocin reduces torsional stress and alters chloroplast transcription *in vivo*. As in several prokaryotic organisms, the chloroplast DNA–dependent RNA polymerase of *C. reinhardtii* is sensitive to rifampicin. Some chloroplast promoters resemble typical prokaryotic promoters with characteristic −10 and −35 boxes. However, several chloroplast promoters lack the −35 box and can be as short as 22 bp. Transcription rates of chloroplast genes vary almost 100-fold. RNA stability can also vary considerably from one transcript to the other and, for all transcripts tested, the stability is significantly higher in dark- than in light-grown cells. Hence, changes in the abundance of chloroplast transcripts are regulated in a gene-specific manner and depend on both environmental and endogenous factors.

Splicing is an important posttranscriptional step in chloroplast gene expression. Most chloroplast introns fall into two major classes, group I and group II, first identified in yeast mitochondrial genes. Members of each class possess a characteristic secondary structure. Whereas introns are present in many chloroplast genes from plants, only three chloroplast genes from *C. reinhardtii* contain introns. Group I introns occur in the 23S ribosomal RNA and *psb*A genes of *C. reinhardtii*. Most of these highly structured introns are able to self-splice *in vitro*. Another unusual property of some of these group I introns is their ability to move at the DNA level, provided a suitable integration site is available. This process, called *intron homing*, was first discovered in yeast mitochondria. In crosses between intron-containing and intronless parents, all the progeny inherit the intron. Intron homing has also been found to occur in bacteriophage T4, in the slime mold *Physarum*, and in the chloroplast and mitochondria of *Chlamydomonas*. All the mobile group I introns contain an ORF encoding a protein with double-stranded DNA endonuclease activity that cleaves the intronless allele at the site at which the intron is inserted. Cleavage triggers transposition of an intron copy to this target site and leads to efficient spreading of the intron to all target sites available. Besides cis-splicing there is trans-splicing in the chloroplast of *C. reinhardtii* during the maturation of the *psa*A message (cf. Sect. 4.1.1).

The chloroplast translational apparatuses of *Chlamydomonas* and plants share

several features with those of prokaryotic organisms: chloroplast ribosomes sediment at 70S and are sensitive to the same spectrum of antibiotics as prokaryotic ribosomes. There is considerable sequence identity between the chloroplast RNAs and bacterial ribosomal RNAs, and some chloroplast translation initiation factors can substitute to some extent for their *E. coli* counterparts *in vitro*. There are, however, some differences. Although several chloroplast genes of *C. reinhardtii* have sequences resembling the Shine–Dalgarno sequences preceding the initiation codon, this is not a general rule. In contrast to *E. coli*, the spacing between the putative Shine–Dalgarno sequence and the initiation codon is not highly conserved. In further contrast to *E. coli*, in which most of the translated messages are polycistronic, chloroplast genes are usually transcribed and translated as monocistronic mRNAs in *C. reinhardtii*.

An unusual feature of *C. reinhardtii* is that expression of the chloroplast *clpP* gene appears to involve protein splicing or posttranslational polypeptide ligation. The *clpP* gene encodes one subunit of the chloroplast ATP-dependent protease. The other subunit is encoded by the nuclear genome. Together, the 5′ and 3′ parts of the *clpP* gene encode a polypeptide that is homologous and colinear with the *clpP* proteins of other organisms. However, the 858 bp middle part of the *clpP* gene does not contribute to the 22 kDa *clpP* subunit. This extra sequence is not excised at the RNA level because it does not display structural features typical of chloroplast introns and because a single transcript accumulates that includes both the *clpP* coding sequence and the extra sequence. Therefore, this region is thought to be removed by protein splicing.

2.3 Mitochondrial Genome

The mitochondrial genome of *C. reinhardtii* consists of 15.8-kb linear molecules and is considerably smaller than the mitochondrial genomes of plants, which range between 200 and 2400 bp. Sequencing of the entire mitochondrial DNA of *C. reinhardtii* has revealed that it encodes eight protein genes, three tRNA genes, and two ribosomal RNA genes (Fig. 4). The proteins encoded by the mitochondrial genome of *C. reinhardtii* are cytochrome *b*, subunit 1 of cytochrome oxidase, five subunits of NADH dehydrogenase, and a reverse transcriptase–like protein whose function is not yet known. The ends of the mitochondrial DNA form an inverted repeat. The most unusual feature of this DNA is that the two mitochondrial ribosomal RNA genes are split into several smaller coding modules, which are scattered over nearly half the mitochondrial genome and are interspersed with protein and tRNA genes. Expression of these multiple gene fragments leads to the accumulation of low- molecular weight subribosomal RNAs that can base-pair with each other to form the characteristic secondary structure of the large and small ribosomal RNAs. The presence of only three mitochondrial tRNA genes strongly suggests that the remaining mitochondrial tRNAs are nucleus-encoded and imported into the mitochondria, as has been demonstrated for some plant mitochondrial tRNAs. Another surprising feature is that, in marked contrast to other organisms, the genes for subunits II and III of cytochrome oxidase and for any of the subunits of ATP synthetase are not encoded by the mitochondrial genome of *C. reinhardtii*.

None of the mitochondrial genes of *C. reinhardtii* contain introns. However, the

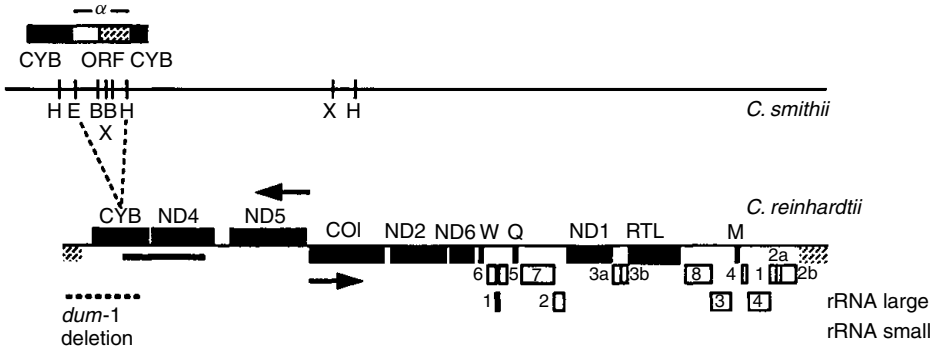

Fig. 4 Physical map of the mitochondrial genomes of *C. reinhardtii* and *C. smithii*. Genes for mitochondrial proteins: CYB, cytochrome *b*; COI, subunit I of cytochrome oxidase; RTL, reverse transcriptase–like protein; ND 1–6, subunits of NADH dehydrogenase. The dispersed arrangement of the ribosomal RNA gene modules is shown; W, Q, M are genes of tRNA Trp, Gln, Met respectively. Restriction site polymorphisms are indicated for *Bam*HI (B), *Eco*RI (E), *Hpa*I (H), and *Xba*I (X). α refers to the intron within the cytochrome *b* gene in *C. smithii* that contains an open reading frame (ORF). Arrows indicate direction of transcription. (Reproduced with permission from E.H. Harris, *Genetic Maps*, Vol. 6, Cold Spring Harbor Press, Plainview, NY, 1993, pp. 2157–3169.)

mitochondrial cytochrome *b* gene of *C. smithii*, which is interfertile with *C. reinhardtii*, contains a mobile group I intron that has properties similar to those of the chloroplast ribosomal intron described in Sect. 2.2. The mitochondrial genomes of *C. eugametos* and *C. moewusii* consist respectively of 24 and 22 kb circular DNA molecules that are colinear with one another. Although these two mitochondrial genomes appear to contain the same set of protein-coding genes as the mitochondrial DNA of *C. reinhardtii*, the genes are strikingly different in their organization.

Mutants with deletions in the apocytochrome *b* gene have been isolated and characterized. These mutants require light for growth and are unable to grow on acetate medium in the dark, indicating that cytochrome *b* is dispensable in the light. Mitochondrial mutants resistant to the respiratory inhibitors myxothiazol and mucidin have been shown to carry point mutations in the cytochrome *b* gene.

3 Recent Technical Advances

A major breakthrough in the area of molecular studies on *Chlamydomonas* was the establishment of reliable methods for transformation of the nuclear, chloroplast, and mitochondrial compartments, and the establishment of a large EST collection.

3.1 Nuclear Transformation

Nuclear transformation can be easily performed with cell wall–deficient *C. reinhardtii* mutants by vortexing the cells with glass beads and DNA or by electroporation. Transformation of the walled strains can also be achieved with the same techniques after removing the wall with autolysin, a glycoprotein that is secreted when gametes of both mating types are mixed together. The most widely used host strains are *arg7*, deficient in argininosuccinate 1yase, and *nit-1*, deficient in nitrate reductase.

Selection is performed on medium lacking arginine or ammonium, respectively, by transformation with the corresponding wild-type genes. It is also possible to transform wild-type strains using markers that confer resistance to several drugs such as emetine, phleomycin, paromomycin, and spectinomycin. The latter three are of bacterial origin and need to be driven by Chlamydomonas promoters for expression in the algal cells. Although several foreign drug-resistant markers have been used successfully in Chlamydomonas cells, efficient expression of foreign genes remains a difficult task. It is also possible to introduce additional genes into the nuclear genome by cotransformation. In most cases, transformation occurs through nonhomologous recombination, as the transforming DNA appears to integrate at random sites of the nuclear genome. This property has been used successfully for tagging genes. In this approach, new mutations are induced through the integration of the transforming DNA into nuclear genes. The bacterial vector sequences in the transforming DNA can then be used as a probe for isolating the mutated gene. Two mobile elements of *C. reinhardtii* – Gulliver, which resembles classical transposable elements, and *TOC1*, which is related to retrotransposons – have been characterized and can also be used for nuclear gene tagging. The high nuclear transformation yield has made it possible to perform gene-rescue experiments by complementing nuclear mutations with genomic cosmid libraries of *C. reinhardtii*.

While nuclear transformation is efficient when cloned *C. reinhardtii* nuclear genes are used as the transforming DNA, it has been difficult to express foreign genes efficiently in this organism even when they are fused to *C. reinhardtii* promoters and 3′ untranslated regions of abundant mRNAs. It is not yet clear whether this is due to the biased codon usage of nuclear genes of *C. reinhardtii*, to methylation of the foreign DNA sequences, or to other factors. Codon bias is clearly important as shown by the successful expression of GFP (green fluorescent protein) when its gene is reconstructed with the *C. reinhardtii* codon usage. Moreover, it is possible to express chimeric genes in the nuclear compartment, provided all gene sequences originate from *C. reinhardtii*. Transcriptional fusions between the *cabII-1* and the *nit-1* genes, coding for a light-harvesting chlorophyll a/b binding protein and the nitrate reductase respectively have been introduced into the nuclear genome and expressed. These chimeric constructs consist of the *cabII-1* promoter region fused at its transcriptional initiation site to the *nit-1* gene. In wild-type cells, expression of the *cabII* gene is strongly increased in the light, whereas the *nit-1* gene is repressed in the presence of ammonium and is expressed in media containing nitrate. Expression of the *nit-1* gene requires a positive-acting regulator encoded by the *nit-2* gene. In the transformants, expression of the chimeric *cabII-1/nit-1* gene was also stimulated by light. However, the *nit-1* mRNA accumulated to a much lower level than the *cabII-1* mRNA. Expression could be slightly stimulated by adding further upstream sequences of the *cabII-1* promoter to the chimeric construct. Expression of the chimeric gene occurred in the presence of ammonium and no longer depended on the *Nit-2* product. This is a useful property since many mutations in *C. reinhardtii* have been isolated in a *nit-1 nit-2* genetic background. Similar chimeric genes have been produced with the tubulin β_2 promoter and the gene encoding periplasmic arylsulfatase. As observed for the tubulin

gene, transcription of the chimeric gene was strongly increased after cells had been deflagellated, although the level of mRNA from the chimeric genes was only 5 to 10% of that from the endogenous β_2 tubulin gene.

3.2 Chloroplast Transformation

Chloroplast transformation of *C. reinhardtii* can be achieved when cells are bombarded with DNA-coated tungsten particles from a particle gun. Chloroplast mutants carrying a defective photosynthetic gene are usually transformed with the corresponding wild-type gene, which integrates into the chloroplast genome by homologous recombination. Alternatively, nonphotosynthetic markers such as ribosomal RNA genes with mutations, conferring resistance to streptomycin and spectinomycin, can be used for selection. Resistance to these antibiotics can also be obtained with the bacterial *aadA* (aminoglycoside adenyl transferase) gene fused to a chloroplast promoter and 5′ leader region. These tools have opened the door for genetic engineering of the chloroplast genome. It is now possible to perform chloroplast gene disruptions and site-directed mutagenesis, and to insert and express foreign genes (e.g. chimeric GUS constructs) at specific sites in the chloroplast genome.

4 Chlamydomonas as a Model System

4.1 Function and Assembly of the Photosynthetic Apparatus

The primary reactions of photosynthesis occur at the thylakoid membranes, in which light energy is collected and converted into chemical energy through charge separations across the membrane and a series of complex oxidoreduction reactions. Ultimately, the process leads to the formation of an electrochemical gradient across this membrane and the production of ATP and NADPH, both of which are required to drive the Calvin cycle, which results in CO_2 fixation and the synthesis of carbohydrates. Four multimolecular complexes are involved in these primary reactions: photosystem II and photosystem I and their associated light-harvesting systems; the cytochrome b_6f complex; and ATP synthetase (Fig. 5). Table 2 lists some of the major subunits of photosystems II and I and their genes.

As in higher plants, the biosynthesis of the photosynthetic apparatus of *C. reinhardtii* occurs through the concerted action of two genetic systems located in the nucleus and chloroplast respectively. Several subunits of the photosynthetic complexes are encoded by the chloroplast genome and translated on 70S chloroplast ribosomes. The remaining subunits are encoded by nuclear genes and translated on cytosolic 80S ribosomes as precursors with a transit peptide at the N-terminal end, which targets the protein to the chloroplast compartment. Upon import of the protein into the chloroplast, the transit peptide is cleaved by a stromal peptidase. Proteins targeted to the thylakoid lumen have a bipartite transit sequence: the N-terminal part acts as a chloroplast transit sequence and is cleaved in the stroma; the C-terminal part always contains a hydrophobic region that is required for translocation across the thylakoid membrane, and this region is cleaved by a second protease, which is tightly associated with the thylakoids. In the final steps, chloroplast- and nuclear-encoded subunits are assembled either in

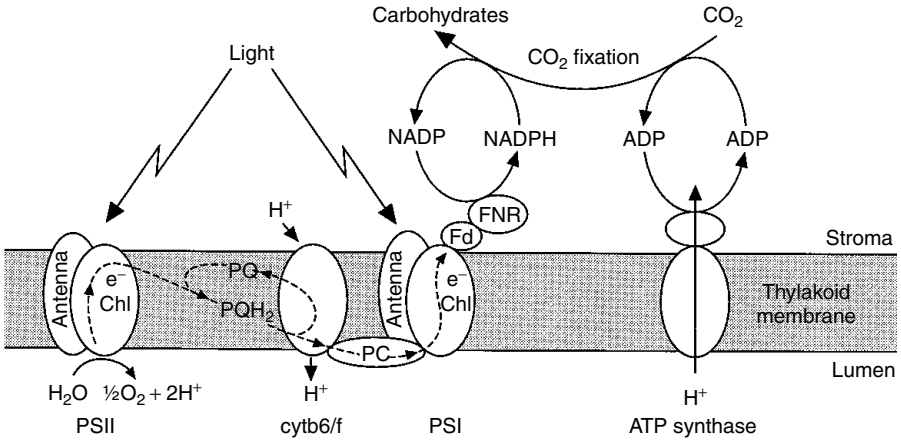

Fig. 5 Scheme of photosynthetic electron transport chain showing the four complexes – photosystem II (PSII) and photosystem I (PSI) with their associated chlorophyll antennae, the cytochrome *b6/f* complex (cytb6/f), and the ATP synthetase. Fd, ferredoxin; FNR, ferredoxin-NADP reductase; PQ, plastoquinone; PQH_2, plastoquinol; chl, chlorophyll.

the stroma or on the thylakoid membranes to form functional protein complexes.

Because photosynthetic function is dispensable when *C. reinhardtii* cells are grown on a medium containing acetate, it has been possible to isolate numerous nuclear and chloroplast mutants deficient in photosynthetic activity. An important feature of the thylakoid membrane is that the physical–chemical properties of its numerous pigments depend critically on the functional state of photosynthetic complexes. Fluorescence has, therefore, been used as a powerful, noninvasive method for screening photosynthetic mutants. Mutations affecting photosynthesis fall into two major classes. The first includes mutations within genes encoding components of the photosynthetic system. The second class includes mostly nuclear mutations that act indirectly on photosynthesis. Many of these mutations affect genes whose products are required for the proper expression of chloroplast genes. These factors appear to act at several posttranscriptional levels (e.g. chloroplast RNA stability, RNA processing and splicing, translation) and, most probably, at the level of assembly of the photosynthetic complexes. Surprisingly, the number of the nuclear loci involved in chloroplast gene expression is quite large and most of their products appear to act in a gene-specific manner (Fig. 6).

4.1.1 Mutations Affecting Structural Photosynthetic Genes

Analysis of photosynthetic mutants has revealed that several are affected in the structural genes of the photosynthetic complexes. Characterized chloroplast mutations comprise deletions, sequence duplications, and single–base pair changes. Among the latter, herbicide-resistant mutants have been especially useful for probing the structure–function relationship of the D1 subunit of photosystem II. Earlier studies had revealed that the absence of any of the subunits from the core complex of photosystem II or I usually leads to a drastic destabilization of the other subunits of the complex. It

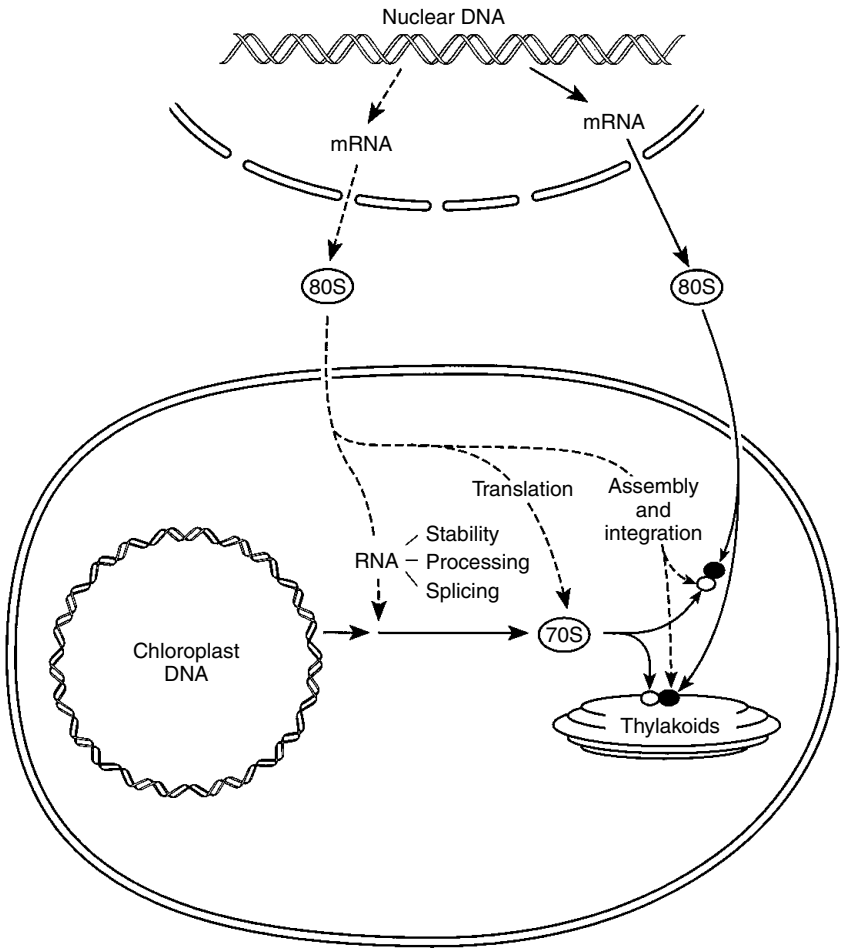

Fig. 6 Biosynthesis of the photosynthetic apparatus. The nucleus and chloroplast are shown in the upper and lower parts, respectively; 70S and 80S represent the chloroplast and cytosolic ribosomes. Synthesis of structural photosynthetic proteins is indicated by continuous lines. The roles of nuclear-encoded factors in posttranscriptional steps of chloroplast gene expression are shown by dashed lines.

has been possible to perform targeted disruptions of several of the smaller photosystem I and II genes in the chloroplast genome of *C. reinhardtii* using the *aad*A expression cassette. It is noteworthy that most of these gene disruptions have a more drastic effect on the stability of the complexes than that of similar disruptions in cyanobacteria. For example, disruption of either the *psbO* or the *psbK* gene in cyanobacteria still allows for photoautotrophic growth in cyanobacteria, but a similar disruption results in the destabilization of photosystem II in *C. reinhardtii*. Similar differences in the stability of the photosystem I complex between *C. reinhardtii* and cyanobacteria have been observed, with mutants carrying directed, specific amino acid substitutions in the PsaC protein, the apoprotein of

the terminal electron acceptors of photosystem I. One possibility is that the clearing system, which recognizes misfolded protein complexes and degrades them subsequently, works more efficiently in *C. reinhardtii* than in cyanobacteria. Site-directed mutagenesis of chloroplast genes encoding subunits of photosystem II, photosystem I, and the cytochrome b_6f complex through chloroplast transformation has been performed extensively and has provided new and important insights into the structure–function relationship of these complexes.

While chloroplast transformation occurs in all cases examined through homologous recombination and allows one to perform gene disruptions or site-directed mutagenesis in the chloroplast genome, nuclear transformation appears to lead, in most cases, to random insertions within the nuclear genome. Attempts to disrupt nuclear genes through homologous recombination have not yet succeeded. However, it has been possible to use transforming DNA as a random mutagen and, thus, to inactivate specific nuclear genes by using suitable screens. This was first achieved with the nuclear *atp*C gene encoding the *CF1* γ subunit of ATP synthetase. Wild-type cells were transformed with a nonfunctional homologue of the *atp*C gene in the presence of carrier DNA. After enrichment for photosynthetic mutants and an immunoscreen, a mutant was isolated that lacked the γ-subunit because its *atp*C gene had been rearranged. Similarly, cells from the *arg*7 mutant were cotransformed with the argininosuccinate lyase gene and the *psa*F gene that had been mutated by three small internal deletions. Transformants were selected for arginine prototrophy and screened for fluorescence patterns typical of photosystem I mutants, and by DNA analysis. One transformant that was obtained lacked *Psa*F and had suffered a large rearrangement at the *Psa*F locus. It appears, therefore, that transformation is a valuable tool for disrupting specific nuclear genes of *C. reinhardtii*, provided suitable screens for the mutant phenotype are available.

4.1.2 Nuclear Mutations Affecting Posttranscriptional Steps in the Expression of Chloroplast Genes

Posttranscriptional steps are important in the control of chloroplast gene expression. *C. reinhardtii* offers unique advantages for genetic analysis of posttranscriptional events. Several nuclear mutations destabilize specifically defined chloroplast mRNAs. Mutations of this type have been reported for *psbB*, *psbD*, *atpA*, *atpB*, and *rbcL* mRNA. In these mutants, all other chloroplast transcripts accumulate normally. It has been possible to identify the target region for *psbD* and *psbB* RNA degradation in nuclear mutants that do not accumulate these mRNAs. For this purpose, either the 5′ or 3′ untranslated regions of these mRNAs were fused to the reporter *aadA*, which confers spectinomycin resistance. These chimeric genes were introduced into the chloroplast genome of a wild-type strain and the transformants of mating-type$^+$ were crossed to either of the original mutants of mating-type$^-$. Because of the uniparental inheritance of the chloroplast genome, all the offspring from these crosses inherit the chloroplast chimeric gene, whereas the nuclear mutations segregate 2 : 2. If the 5′ untranslated region of *psbD* or *psbB* is sufficient to confer instability to the chimeric RNA, there will be cosegregation between spectinomycin sensitivity and photosynthetic deficiency. This cosegregation has indeed been shown to occur among the progeny, and the loss of chimeric RNA in

the mutant nuclear background has been confirmed. Recently, the genes that are deficient in these two mutants have been cloned and characterized. In both cases, they encode proteins consisting mainly of 9–10 TPR (tetratricopeptide) repeats that are present in a wide range of proteins with distinct biological function and that appear to play an important role in protein–protein interactions.

A molecular genetic analysis is also feasible at the level of RNA processing or splicing. The *psaA* gene, encoding one of the reaction center subunits of photosystem I, consists of three exons that are widely scattered on the chloroplast genome of *C. reinhardtii*. Each exon is flanked by sequences characteristic of group II introns, and maturation of the *psaA* message depends on two trans-splicing reactions. Surprisingly, intron 1 itself has a tripartite structure: the 5′ part is fused to exon 1; the middle part is encoded by a locus, *tscA*, that is distant from both exons 1 and 2; and the 3′ part is fused to exon 2 (Fig. 7). The second *psaA* intron has a bipartite

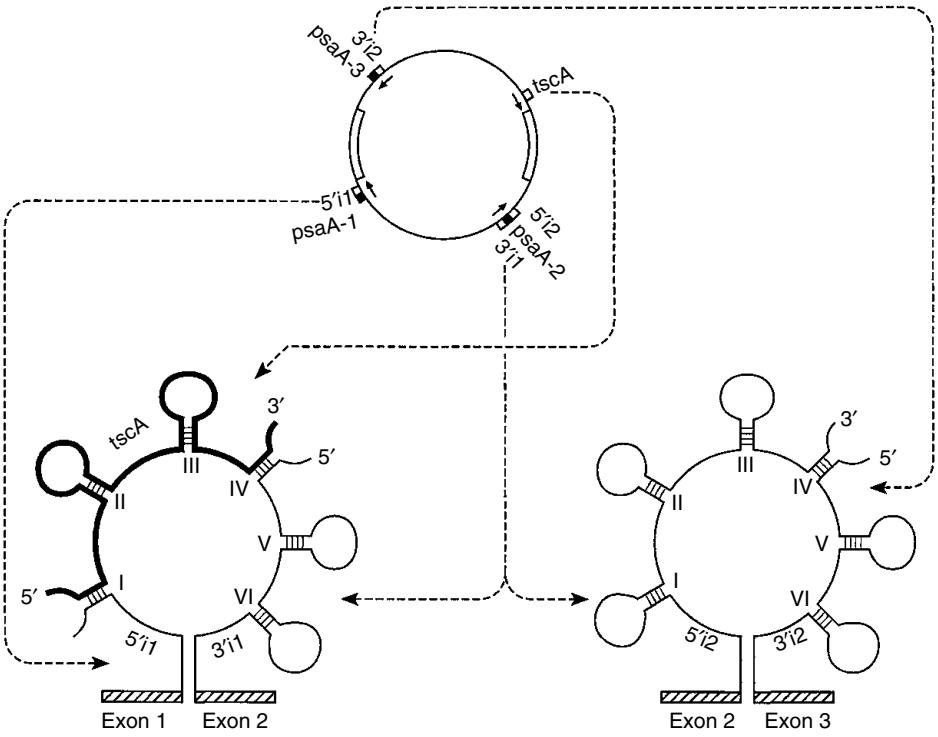

Fig. 7 Maturation of the chloroplast *psaA* mRNA of *C. reinhardtii*. Upper part: the three exons *psaA-1*, *-2*, *-3* and their flanking group II intron sequences (5′i1, 3′i1, 5′i2, 3′i2) and *tscA* (not drawn to scale) are shown on the circular chloroplast genome. Arrows indicate the direction of transcription, and the two open boxes represent the two segments of the chloroplast inverted repeat. Lower part: secondary structure of the split-group II intron of *psaA* showing the six characteristic domains. Intron 1 (left) has a tripartite structure: the *tscA* RNA (heavy line) base-pairs with the 5′ region of intron 1 within domain I, completes the catalytic core by forming domains II and III, and pairs with the 3′ part of intron 1 within domain IV. Intron 2 (right) has a bipartite structure; pairing occurs within domain IV.

structure. Numerous mutants affected in *psaA* trans-splicing have been isolated and can be grouped into three classes. In the first are mutants unable to splice exons 1 and 2, the second comprises mutants unable to splice exons 2 and 3, and the third consists of mutants unable to perform either trans-splicing reaction. At least 14 nuclear loci are involved in this complex maturation pathway. Whether the unusual split structure of the *psaA* gene reflects an ancient gene structure or whether it was created through division of an ancestral *psaA* gene by DNA rearrangements remains an open question. The nuclear genes of several of the factors involved in trans-splicing have been cloned and characterized. Some of them resemble known proteins involved in RNA metabolism such a pseudouridine synthases, although the enzymatic activity is not required for trans-splicing. Whether these proteins have a dual role in chloroplast RNA maturation is not yet clear. Some of these factors are part of high molecular weight RNA protein complexes that are reminiscent of snRNPs in eukaryotic cells, although no significant sequence identity is apparent between the subunits of these complexes.

Mutants affected in chloroplast translation have also been examined. These mutants were first identified on the basis of pulse labeling of cells in the presence of an inhibitor of cytoplasmic protein synthesis. Under these conditions, only polypeptides translated in the chloroplast compartment are labeled. From the labeling patterns, it is, however, difficult to distinguish mutants truly affected in translation from those having increased protein turnover. By using a strategy resembling the one based on the use of chimeric genes outlined earlier for the nuclear mutant deficient in *psbD* RNA accumulation, it has recently been shown that some of the mutants are indeed affected at the level of initiation of translation. Several of the trans-acting factors have been recently identified (Table 2).

4.1.3 Metal Ion Control of Photosynthetic Gene Expression

The copper-containing protein plastocyanin catalyzes electron transfer between the cytochrome b_6f complex and photosystem I (Fig. 5). Growth of terrestrial plants in copper-deficient habitats leads to symptoms of copper deficiency. However, *Chlamydomonas*, like other aquatic algae and cyanobacteria, remains photosynthetically competent under copper-deficient growth conditions. This is because, in the absence of copper, the alga expresses the heme-containing cytochrome c_6, an alternate electron carrier to plastocyanin. Although plastocyanin is still expressed under conditions of copper deficiency, the apoprotein is highly unstable and is rapidly degraded. Expression of cytochrome c_6 proceeds only in the absence of copper and is regulated at the transcriptional level. The cupric ion–responsive promoter of the cytochrome c_6 gene displays unique metal specificity and high sensitivity; in addition, it governs reciprocal control of synthesis of two proteins, cytochrome c_6 and plastocyanin, which are distinct although functionally equivalent. On the basis of the observation that the amount of copper ions needed to repress cytochrome c_6 transcription matches the amount of plastocyanin in *Chlamydomonas* cells, it has been proposed that repression of transcription requires a copper-binding factor that is titrated by copper only after plastocyanin has accumulated to a level needed for photosynthesis. Therefore, the control of cytochrome c_6 expression results mainly from a direct cellular sensing of available copper rather than indirectly as

a consequence of loss of plastocyanin or decreased photosynthetic activity in copper-deficient cells.

4.1.4 Adaptation of the Photosynthetic Apparatus to Changes in Light Conditions

Like other algae and land plants, *C. reinhardtii* has the remarkable ability to adapt its photosynthetic machinery to changes in light quantity and quality. Photosynthetic organisms can dissipate the light excitation energy by photochemistry, by fluorescence, or by nonphotochemical quenching. The latter occurs under excessive illumination, is triggered by the increased proton gradient across the thylakoid membrane, and involves a reversible structural modification of the carotenoids through the xanthophyll cycle. This leads to an increased heat dissipation of the excitation energy and lowers the fluorescence emission and the photooxidative damage within the photosynthetic reaction centers. A genetic approach has identified several factors involved in nonphotochemical quenching and has provided direct evidence for the involvement of the xanthophylls in this process.

Photosystem II and photosystem I act in series in the photosynthetic electron transport chain, and they are connected to two distinct antennae systems with different light absorption properties. Upon a change in the spectral quality of the exciting light, a reorganization of the antennae occurs, insuring a balanced excitation of the two photosystems and hence an optimal photosynthetic quantum yield. This process is called *state transition* and involves the displacement of the antenna of photosystem II to photosystem I under conditions in which photosystem II is overstimulated relative to photosystem I. A key step of this mechanism is the activation of a kinase that specifically phosphorylates the N-terminal end of the LHCII proteins. The activation is triggered through a signal transduction chain that involves the redox state of the plastoquinone pool and a functional cytochrome b_6f complex. Attempts to isolate the kinase by biochemical means have failed. However, a genetic approach has identified several mutants that are deficient in state transition and blocked in the phosphorylation of LHCII. Recently, the gene deficient in one of these mutants has been isolated and characterized and has been found to encode a thylakoid-associated kinase. Mutants of this sort offer promising possibilities for identifying the different factors involved in state transition.

4.1.5 Heteroplasmicity of the Chloroplast Genome

It is generally assumed that chloroplast genomes consist of identical copies of single DNA molecules. The predominantly uniparental inheritance of chloroplast genomes could easily maintain such homoplasmicity. Although most heteroplasmic markers segregate rapidly to form homoplasmic cells, cases of stable heteroplasmicity can occur in the chloroplast of *C. reinhardtii*.

Mutants deficient in photosynthetic activity have been shown to arise from nonsense mutations within the chloroplast *rbcL* gene encoding the large subunit of ribulose 1,5-bisphosphorate carboxylase/oxygenase. In these mutants, the holoenzyme is undetectable because of rapid degradation of the unassembled and truncated subunits. Photosynthetically competent suppressors of these nonsense mutants have been found to be heteroplasmic, giving rise to both mutant and suppressor cells during divisions under

nonselective growth conditions. No homoplasmic suppressor segregants could be obtained even after repeated cloning or crosses under phototrophic growth conditions. In contrast, photosynthetic-deficient segregants quickly became homoplasmic under heterotrophic growth conditions. The molecular basis of the heteroplasmicity has been determined for a suppressor of an amber (UAG) mutation. In this suppressor, the original mutation is still present in all chloroplast DNA copies. However, 70% of the copies of tRNA *trp* have the tryptophan CCA anticodon changed to the amber-specific CUA. Under phototrophic growth conditions, therefore, stable heteroplasmicity can arise as a balanced polymorphism of suppressor and wild-type alleles of a tRNA gene within the chloroplast genome. In this case, the suppressor allele restores ribulose 1,5-bisphosphate carboxylase, whereas the wild-type allele is required for normal protein synthesis. When photosynthesis is not required, the suppressor tRNA allele is lost because of random segregation, giving rise to homoplasmic photosynthetic-deficient segregants.

As mentioned earlier, it is possible to disrupt chloroplast genes encoding components of the photosynthetic apparatus using transformation and the *aadA* expression cassette that confers spectinomycin resistance in the chloroplast. The transformants that are obtained usually become homoplasmic after a few cloning steps. However, disruptions of chloroplast genes that are essential under all growth conditions never give rise to homoplasmic transformants. In this case, stable heteroplasmicity is maintained as long as spectinomycin is present in the growth medium. Stable heteroplasmicity can, therefore, be used for identifying chloroplast genes encoding essential functions.

4.2 Function and Assembly of the Flagellar Apparatus

Chlamydomonas reinhardtii possesses two flagella, located at the anterior end of the cell, that are assembled on basal bodies. During cell division, basal bodies migrate to the interior of the cell and function as centrioles by organizing the spindle apparatus. The flagellar system of *Chlamydomonas* has proven to be particularly well suited for studying microtubule assembly and function, and motility. This is because flagellar biosynthesis can be readily synchronized, and numerous mutants affected in the function and assembly of the flagellar apparatus have been isolated. These mutants can be separated into two major classes: those with abnormal or no motility, usually called *paralyzed mutants* (with the acronym pf), and those defective in flagellar assembly (fla).

Extensive ultrastructural and biochemical studies have revealed that the flagellae consist of a set of nine outer doublets, each consisting of two microtubules A and B, and a central pair of microtubules (Fig. 8). Outer and inner arms arise from A microtubules of the outer doublets. The outer arms, which comprise dyneins and large multisubunit ATPases, extend toward the B tubules, where they act to generate interdoublet sliding. Outer-arm dyneins consist of α-, β-, and γ-heavy chains and of intermediate and light chains. Partial cDNA sequences of the γ-heavy chain and of an unidentified heavy chain of *C. reinhardtii* have revealed that these proteins have at least two conserved domains corresponding to the ATP hydrolytic site and to a region related to the microtubule binding domain of the kinesin superfamily. A mutant lacking outer arms could be rescued by transformation with a genomic clone

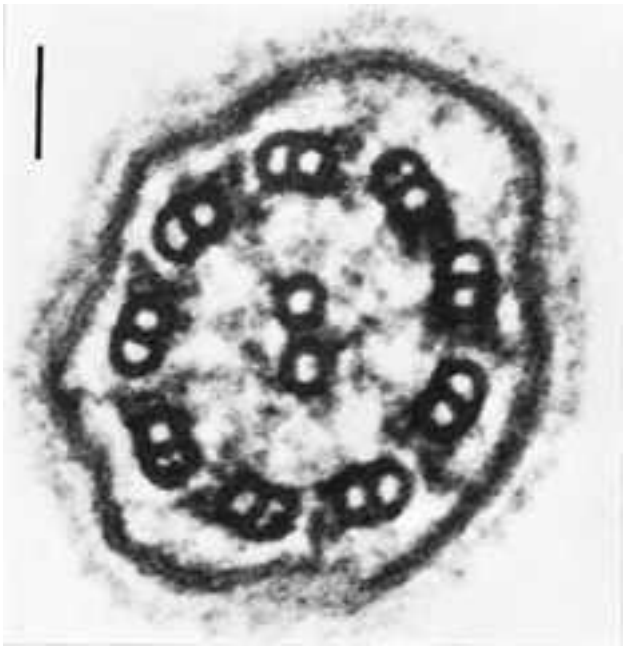

Fig. 8 Cross section of the *C. reinhardtii* flagellum showing the nine outer doublets with inner and outer dynein arms and the radial spokes extending toward the central pair of tubules; bar indicates 0.05 m. (Reproduced with permission from Witman, in *Ciliary and Flagellar Membranes*, R.A. Bloodgood, Ed., Plenum Press, New York, 1990, pp. 1–30.)

encoding a 69 kDa intermediate chain, thus showing that a defect in this chain can interfere with outer-arm assembly. The α-heavy chain does not appear to be required for stable outer-arm assembly because a mutant missing the α-chain and its associated 16 kDa light chain is still able to form a partially functional truncated outer arm. Two morphologically different types of inner arm have been identified. However, biochemical and genetic studies indicate the existence of at least five different types of inner arms, consisting of homodimers and heterodimers of six inner-arm heavy chains, and of smaller polypeptides. Mutants lacking the outer arms or some of the inner arms are still mobile, showing that none of these arms is essential for interdoublet sliding. Since the former are affected in flagellar beat frequency and the latter in the waveform, however, it is clear that functional differences exist between the arms.

The most abundant flagellar proteins are the α- and β-tubulins, each of which is encoded by two genes. Both β-genes encode identical proteins, while the products of the two α-genes differ by two amino acids. Besides the tubulins, as many as 250 to 300 distinct flagellar polypeptides can be resolved. Analysis of many paralyzed mutants has revealed that some are deficient in specific axonemal components. The defects observed in these mutants have been found to cosegregate with the mutant phenotype. Mutants lacking the central pair of

tubules have rigid flagellae, while mutants lacking functional radial spokes are usually paralyzed. Radial spokes participate in the regulation of dynein arm activity and, thus, in flagellar bending. The radial spoke consists of a thin stalk attached to the A tubule of the outer doublet and of a head that projects close to the central pair of microtubules. A set of 17 axonemal polypeptides appears to be associated with radial spokes because radial spokeless mutants lack all these polypeptides. Several of the corresponding genes have been isolated and characterized.

A common feature observed in many paralyzed mutants is the loss of a set of polypeptides corresponding to an entire complex, presumably because loss of one subunit leads to increased turnover of the other subunits or because the missing subunit is important for anchoring the complex. In some cases, it has been possible to identify the specific polypeptide that is affected by the mutation by performing a dikaryon rescue experiment. During wild-type crosses, biflagellate gametes of plus and minus mating-type produce quadriflagellate temporary dikaryons. It was originally shown that flagellar motility is restored in pairwise crosses between paralyzed mutants and the wild-type, suggesting that the polypeptides contributed by both parents can be assembled into functional flagellar complexes after mating. This approach has been extended by labeling the proteins of the mutant and by mating the labeled mutant cells with unlabeled wild-type cells. Restoration of flagellar function is allowed to occur in the presence of a protein synthesis inhibitor to block new protein synthesis. Under these conditions, the polypeptide that is deficient in the mutant appears only in the unlabeled form, since it is derived from the wild-type parent, whereas the other normal proteins from the mutant are labeled.

Dikaryon rescue has also been used to study the polarity of assembly of the flagellar microtubules. In these studies, transformants that expressed an epitope-tagged α-tubulin were mated to recipient cells that had half-length flagellae. Upon fusion, the shorter pair of flagellae grew to full length using a common pool of precursors that included epitope-tagged tubulin. Immunodetection methods revealed that the flagellar microtubules elongate by addition of new subunits at their distal end. Similar results have been obtained with the assembly of radial spoke proteins onto radial spokeless full-length flagella, suggesting that both tubulin and radial spoke proteins are transported to the distal end of the flagellum prior to their assembly into flagellar structures.

Because flagellar structure has been conserved throughout evolution, results obtained with *Chlamydomonas* are relevant for understanding human diseases. These include primary ciliary dyskinesis that affects the motility of cilia, polycystic kidney disease that involves, in some cases, a defect in the assembly of the primary cilia, and retinitis pigmentosa that causes retinal degeneration through a defect in transport of proteins through the connecting cilium of the photoreceptor cells and thereby leads to blindness. Several of the *Chlamydomonas* flagellar proteins are remarkably similar to the human proteins associated with some of these diseases.

Other mutations affecting the size of the flagella have also been examined. Some of these mutants have short flagella but otherwise normal axonemal structures. Others, called *stumpy mutants*, have very short, nonfunctional flagella. Mutants lacking flagella, called *bald mutants*, are deficient in

basal bodies. Mutants with a variable number of flagella and basal bodies have also been isolated. One of them, *vfl2*, has a single amino acid change in centrin, a 20 kDa calcium binding protein involved in the formation of fibers that show calcium-dependent contraction. The *vfl2* mutant has structural defects in the fibrous structures in which centrin is present: the nucleobasal body connectors, the distal striated fibers that link the two basal bodies together, and the flagellar transition region between the basal bodies and their flagella. This mutant is also defective in basal body localization and/or segregation.

While most of the nuclear mutations affecting flagellar function and assembly map on various chromosomes, several are linked together on a linkage group called the *uni* linkage group. The name is derived from the *uni* mutation, which affects the assembly of one basal body and, consequently, leads to the appearance of uniflagellated cells. The high degree of clustering of functionally related genes on the *uni* linkage group is unusual for eukaryotic chromosomes.

Fragments of the *uni* linkage group have been cloned by taking advantage of the restriction fragment length polymorphisms that exist between *C. reinhardtii* and *C. smithii*. Two genetically marked strains of these two species were crossed, and the progeny containing the *uni* linkage markers from the *C. smithii* parent and the other nuclear markers from the *C. reinhardtii* parent were selected and backcrossed with the *C. reinhardtii* parent. By repeating these backcrosses several times, it has been possible to construct a strain with a *uni* linkage group derived from *C. smithii* in a nuclear genetic background that derives mostly from *C. reinhardtii*. A repetitive element present in both parental strains was then used to detect RFLPs linked to the *uni* linkage group and to clone DNA fragments of the *uni* linkage group. These fragments were used as probes to determine that the *uni* chromosome is a linear DNA molecule consisting of 6 to 9 megabase pairs.

5 Perspectives

Chlamydomonas has emerged as an attractive model system for studies of the molecular and cellular biology of eukaryotic photosynthetic cells. This alga can be manipulated with relative ease at the biochemical, molecular, and genetic levels. It is, at present, the only organism in which nuclear, chloroplast, and mitochondrial transformations are feasible. The ability to introduce genetically modified genes into *C. reinhardtii* mutant strains in which the endogenous gene is defective can provide important insights into the structure–function relations of the corresponding proteins. In this respect, this alga will remain valuable for studies on flagellar function and assembly, especially for understanding the complex functional interrelationships between the various flagellar subcomplexes *in vivo*. An important point is that the use of *C. reinhardtii* can also be extended to the understanding of human diseases associated with flagellar or ciliary dysfunction.

Because the photosynthetic apparatus of *C. reinhardtii* is very similar to its homologue in higher plants, this alga is also an excellent system for studying the biogenesis and function of the photosynthetic complexes, and for investigating more generally the genetic interactions between the nuclear, chloroplast, and mitochondrial compartments. Other areas of research for which *Chlamydomonas* is

uniquely suited are phototaxis, cell wall synthesis, mating reactions and gametogenesis, and the metabolism of carbon, nitrogen, and sulfur. It is anticipated that the forthcoming sequencing of the nuclear genome of *C. reinhardtii* will further enhance the power of this unicellular alga for biological studies.

Keywords

Constrained Diffusion
Type of Brownian motion in which an object undergoes random, thermally driven movements, just as in free diffusion, except that the object is prevented from diffusing outside a limited region of space. Chromatin motion during interphase appears to be dominated by this type of motion.

FISH (Fluorescence In Situ Hybridization)
A method of visualizing the position of individual chromosome loci during interphase by hybridization with an exogenous DNA probe that is either itself fluorescently labeled, or that contains an epitope that can be detected with fluorescent probes.

Heterochromatin
Regions of chromatin containing mostly simple-sequence repeated DNA that is highly compacted during interphase. Most heterochromatin is transcriptionally inactive.

Nuclear Envelope
The double bilayer that surrounds the nucleus. The ER derived from endoplasmic reticulum, is organized by a protein-based network containing nuclear lamins, and is penetrated by pores called *nuclear pore complexes*, which allow import and export of proteins and RNA molecules.

Nuclear Matrix
A putative internal protein-based network that criss-crosses the nuclear lumen and may help organize chromatin.

Rabl Configuration
The polarized organization of chromosomes in the nucleus, with centromeres clustered at one end of the nucleus and telomeres at the other. The Rabl configuration is a remnant of the anaphase chromosome configuration.

The interphase nucleus provides the structural context for chromosome biology, including gene expression and recombination. The organization of chromosomes within the nucleus is not random. Instead, chromosomes are organized by specific constraints, including interactions of specific loci with the nuclear envelope. This

interaction may involve both nuclear lamins and nuclear pore complexes. Specific nuclear envelope attachments, together with a persisting remnant of the anaphase chromosome configuration, leads to chromosomes being organized into nonoverlapping territories with specific orientations. Superimposed on this organization is a high degree of chromosome mobility driven by diffusion. Because chromosomes are constrained by nuclear envelope attachments, their diffusion is constrained, with each locus able to explore only a limited subregion of the nucleus. This constrained mobility, together with the nonrandom positional organization of chromosomes, predicts a high degree of nonrandomness in the pattern of interchromosomal interactions.

1 Introduction

The genome is packaged within the nucleus on many levels. Not only is the DNA wound around nucleosomes and compacted into chromatin, the chromosomes themselves are arranged within the nucleus in a defined pattern. This nuclear organization is set up and maintained by interactions between chromosomes and the nuclear envelope (NE) and possibly an internal nuclear matrix. However, chromosomes are not absolutely fixed, but are able to undergo a certain degree of constrained motion, which allows interactions between chromosomes to take place. This combination of specific positioning and constrained movement leads to a dynamic view of nuclear organization in which large-scale chromosome organization can play a decisive role in regulating gene expression and chromosome interactions.

2 Chromosome Positioning

2.1 Analysis of Polytene Chromosomes

Determining the arrangement of interphase chromosomes is a challenging problem, because during interphase the chromosomes decondense and thus become difficult to visualize. Early dramatic evidence for nonrandom chromosome arrangement came from analysis of *Drosophila* polytene chromosomes in three dimensions. Polytene chromosomes are large and compact and easy to image inside living cells. Moreover, the well-known banding pattern of polytene chromosomes allowed the position of each locus, defined cytologically by banding pattern, to be determined in three-dimensional space, thus projecting the one-dimensional genetic map onto a three-dimensional map of the nucleus. These studies were among the first studies ever to use three-dimensional fluorescence microscopy. On the basis of this type of analysis, it was found that the arrangement of chromosomes was different in different nuclei, indicating that the position of a locus was not rigidly predetermined. But although the arrangements were variable, they were not entirely random either. For one thing, the chromosomes followed a polarized orientation in the nucleus, with centromeres at one end of the nucleus, and telomeres at the other. Both the polarized arrangement of chromosomes and their separation into distinct domains probably reflects a persistence of

their arrangement in mitosis, and suggests that the chromatin did not undergo extensive rearrangement within the nucleus following decondensation in telophase. In addition, the chromosomes occupied separate domains and were not intertwined. Finally, chromosomes contacted the NE at particular loci. These studies in polytene chromosomes showed chromosomes were organized according to two fundamental organizational principles: specific contacts with the NE and persistence of the mitotic chromosome arrangement.

2.2 Fluorescence *In Situ* Hybridization (FISH)

Following the initial work in polytene chromosomes, great interest was created in testing whether the same conclusions would hold in ordinary nonpolytene chromosomes during interphase. Measuring interphase chromosome arrangements in normal cells required FISH in which DNA probes specific for a given locus are hybridized onto intact nuclei and detected using fluorescent probes. One potential danger in using FISH is that the harsh conditions needed for hybridization can often disrupt the organization of the nucleus. This is particularly true of methods that involve air-drying or acid treatments during fixation, and it is always worthwhile, in assessing the value of a given FISH analysis, to examine the protocol in detail. It is likely that some of the published studies that have failed to observe reproducible nuclear organization failed because of overly harsh sample preparation that destroys the three-dimensional structure. Certainly, any procedure in which nuclei are flattened or spread will, by definition, destroy the three-dimensional structure. Fortunately, the study of nuclear organization by FISH has been greatly facilitated by the development of fixation and hybridization procedures that preserve the three-dimensional structure of the nucleus. Many such studies, summarized below, have shown that the two main results of the polytene studies, namely, NE interactions and persistence of mitotic arrangement, also hold true in other cell types.

2.3 Interactions with the Nuclear Envelope

Many studies have used FISH to show specific chromosome regions are localized to the NE, which probably accounts for the earlier observations using electron microscopy that revealed multiple sites of chromatin–NE contact in the nucleus. In most cases, we do not yet know what DNA sequences determine this interaction, although several studies have now suggested that silenced chromatin may confer NE attachment (see below).

A priori, if a given locus is found near the NE, this could either reflect an interaction of the chromatin with the NE, or alternatively it might simply reflect a nonrandom radial positioning within the nucleus due to either the intrinsic folding of the chromosomes or perhaps due to exclusion from the nuclear interior of loci that cannot interact with some internal structure. However, all available evidence suggests that the localization of chromatin near the NE involves an actual physical interaction between chromatin and some component of the NE. Polytene chromosomes have been clearly shown to be physically stuck onto the NE at discrete sites. This conclusion is also supported by studies of interphase chromatin movement *in vivo* in which loci near the NE tend to move significantly less than more internal loci.

It is likely that loci targeted to the NE will find themselves in a highly specific subenvironment within the nucleus, which might have properties different from those in the nuclear interior. Certainly, such loci would have the opportunity to interact with many proteins of the NE that would be effectively invisible to loci that were found in the nuclear interior. Direct interactions with NE proteins are indeed thought to play a role in gene silencing, as discussed below. However, in addition to a direct effect on the NE-targeted loci, the attachment of chromosomes to the NE forces the rest of the chromosome into a nonrandom radial positioning, in which even loci not actually attached to the NE will tend to occupy specific radial distances relative to the surface. This nonrandom radial positioning has been systematically explored in *Drosophila*, but has also been seen in mammalian cells. This nonrandom radial position is likely to have significant effects on chromosome interactions (see Sect. 6 below).

2.4 Retention of Mitotic Chromosome Geometry

During anaphase, chromosomes become aligned such that all centromeres cluster together as they move to the pole, while the telomeres trail behind. When the chromatin decondenses in telophase, this arrangement should result in a polarized nucleus in which telomeres are at one side of the nucleus and centromeres at another. This is generally referred to as the *Rabl Configuration* after its discoverer, Carl Rabl. This Rabl configuration has been clearly demonstrated using FISH in a wide range of cell types. The Rabl orientation affects not just the position of centromeres and telomeres, but of all the chromatin in between. This has been most clearly shown in *Drosophila* embryos, in which loci spanning a chromosome arm were shown to occupy a precise position along the nuclear axis, in an order that follows precisely their linear order along the chromosome. The Rabl arrangement is most dramatic in cells that are dividing actively, and tends to become less obvious in cells that have arrested in the cell cycle. This is likely to reflect the slow diffusive motion of chromatin during interphase, such that the longer a cell remains arrested following division, the more the mitotic chromosome arrangement becomes distorted.

In addition to aligning during mitosis, chromosomes also become condensed into spatially separated objects. When the chromatin decondenses in telophase, this spatial separation tends to force the chromosomes into nonoverlapping regions within the nucleus. Indeed, a variation on FISH called chromosome painting, in which entire chromosomes are visualized using a pool of DNA probes, has shown that interphase chromosomes generally remain separated into nonoverlapping "territories."

The combined effect of specific NE interactions and the retention of mitotic arrangement is to set up a highly nonrandom arrangement of chromosomes within the nucleus, such that different loci tend to occupy specific subregions of the nucleus. Because this positioning is a by-product of large-scale chromosome arrangements, there tends to be a lot of variability in the position of individual loci, such that the nonrandomness of nuclear architecture is best viewed as a statistical trend, rather than as an absolute predetermined arrangement.

3
Molecular Interactions That Specify Nuclear Architecture

Nuclear architecture is maintained by interactions with the NE and possibly an internal nuclear matrix. Many studies over the past few decades have revealed a number of candidate molecules that might account for these interactions. Such studies will really be the key to understanding the function of nuclear architecture, since in principle, the identification of the molecules involved should allow the architecture to be perturbed in a reproducible way and the effects of this perturbation tested.

3.1
Nuclear Lamins

What part of the NE is responsible for binding chromatin? The nuclear lamins, a family of intermediate filament-like proteins that form a network on the inner surface of the NE, are able to bind specific DNA sequences *in vitro* as well as histones. Several lamin-associated proteins can bind DNA or chromatin. It remains unclear, however, whether these interactions really occur in living cells. Moreover, since lamins are thought to be involved in reassembling the nucleus around chromosomes during telophase, it is important to distinguish between chromatin–lamin interactions that are involved solely in nuclear reassembly. A FISH analysis of nuclear organization during nuclear reassembly in *Drosophila* embryos has shown that the loci that interact with the NE during interphase are not the same as the loci that interact with the NE during nuclear reassembly.

3.2
Nuclear Pores

Nuclear pore complexes (NPCs) also appear capable of interacting with chromatin. For example, one NPC protein binds DNA *in vitro*. Moreover, the telomere protein yKu70 can bind to the NPC associated protein Mlp2, which is attached to the NPC via an interaction with the nucleoporin Nup145. All three of these proteins are needed for telomeres to interact with the NE. In electron microscopy studies of the NE, the nuclear pores are seen to extend long processes into the nuclear interior, and these may be likely candidates for the specific structures that interact with chromatin. Because both the nuclear lamins and the NPCs can associate with chromatin, it is critical to distinguish which set of molecules is required for a given chromatin–NE interaction.

3.3
Nuclear Matrix

In addition to interactions with the NE, chromatin might also interact with an internal structure within the nucleus called the *nuclear matrix*. The nuclear matrix was first defined as the insoluble residue that remains after isolated nuclei are heavily extracted, and so its relevance to actual structures *in vivo* has never been very clear. A network of fibers has been seen in nuclei that might correspond to the matrix, but only when using unusual resinless embedding procedures for electron microscopy, which raise concerns about potential artifacts. Two proteins in *Drosophila*, CP60 and CP190, appear to form a network within nuclei of living *Drosophila* embryos, and this network persists in the shape of the nucleus even after the NE has broken down and the chromosomes have congressed to

the metaphase plate. CP60 and CP190 are components of the nuclear matrix defined biochemically, and thus may represent a true matrix that exists as a coherent structure in living cells. This possibility deserves more detailed investigation.

4
Interphase Chromatin Movement

The only way for chromosomes to be held in a defined arrangement is for their mobility to be constricted. Otherwise, one would expect the chromatin to diffuse throughout the nucleus, like polymers in a polymer melt, and rapidly randomize any initially nonrandom configuration.

4.1
Evidence for Chromatin Immobilization

Early cytological evidence suggested that interphase chromosomes were fairly immobile as judged by the similarity of chromosome arrangements in successive mitoses by the separation of parental genomes in the first few divisions after fertilization. Modern biophysical methods, including photobleaching and *in vivo* chromosome visualization, have confirmed the early impression that chromosome movement is constricted during interphase.

4.2
Evidence for Chromatin Diffusion

However, more detailed measurement of interphase chromatin movement in living cells, based on an application of submicron single-particle tracking techniques to individual loci tracked using a green fluorescent protein (GFP) tagging system, revealed that interphase chromatin does in fact undergo substantial and rapid diffusion, but this diffusion is constrained such that a given locus can only diffuse within a small subregion of the nucleus. In yeast and *Drosophila*, chromatin moved with a diffusion constant of approximately 10^{-11} cm^2 s^{-1} because of thermally driven Brownian motion. But this diffusion was confined to a subregion with a radius of 0.3 μm for yeast and 0.9 μm for *Drosophila*, roughly equal to 1to 5% of the nuclear volume. Following this first analysis of chromatin diffusion in yeast and *Drosophila*, subsequent analyses have confirmed the result that interphase chromatin can diffuse within a confined region in a wide range of cell types. More detailed analysis has shown that the details of chromatin diffusion depend on the timescale, and that at very short timescales chromatin movement is highly constrained, whereas at longer timescales, chromatin is freer to diffuse over larger distances. This suggests that chromatin diffusion at short timescales is constrained by interaction with a structure (e.g. the nuclear lamina) that itself undergoes slow random movements. Nuclear pores have been shown to turn over at a slow but detectable rate such that if chromatin were constrained by interactions with NPCs, then the slow rearrangement of the nuclear pores could account for the relaxation of chromatin constraint on long timescales. The idea that chromatin diffusion is constrained via interactions with the NE is supported by two recent studies that found that diffusion of chromatin loci associated with the NE is significantly more constrained than other loci. In the most dramatic example, Chubb and coworkers showed that NE-associated chromatin has exactly the same diffusion constant as other chromatin, but is confined to a much smaller subregion of the nucleus.

4.3
Evidence for Active Chromatin Movement

In addition to this constrained diffusion, it also appears that loci can undergo active directed movements, at least in some cases. When centromeres in animal cells were tracked *in vivo*, it was found that the centromeres occasionally experienced persistent directed movements in the interphase nucleus. Another study showed large directed shifts in gene position during the mid-blastula transition in *Drosophila* embryos, possibly driven by the force of heterochromatin condensation.

5
Regulation of Gene Expression by Nuclear Architecture

5.1
Role of Nuclear Envelope Interactions in Gene Silencing

Heterochromatin, the highly condensed transcriptionally silenced regions of the genome, is generally seen near the NE in electron microscopy studies. Indeed, insertion of a block of heterochromatin into a euchromatic position is sufficient to locate the whole region onto the NE. More specific FISH studies of individual chromosomes have found that gene-poor chromosomes with reduced overall transcription tend to be NE associated. These results raise the possibility that the NE might play some role in establishment of silenced heterochromatin. Indeed, targeting a reporter gene to the NE by means of an NE-interacting DNA-binding fusion protein results in silencing of the gene, and induced transcriptional activation of a reporter locus caused the locus to dissociate from the NE and move to the nuclear interior. Mutations in the telomere-binding protein dimer yKu70/yKu80 and the NPC associated proteins Mlp1/Mlp2 cause telomeres to dissociate from the NE and result in loss of telomeric silencing, again suggesting that NE interactions play some role in gene silencing. The SIR3 and SIR4 silencing proteins in yeast are associated with the NE, which suggests a simple model that genes associated with the NE experience a higher local concentration of silencing proteins.

Another potential example of the NE playing a role in gene repression comes from studies of the lamin-associated protein 2 beta (LAP2β), an integral membrane protein component of the nuclear lamina. Ectopic expression of LAP2β and its binding partner GCL (germ cell-less) in cells that do not normally express GCL, reduces transcriptional induction by the E2F-DP complex, which binds GCL. This raises the possibility that Lap2β and GCL could recruit E2F-regulated genes to the NE where they would become silenced.

5.2
Gene Gating

Although most studies suggest that the NE exerts a negative effect on gene expression, a possible positive correlation between gene expression and NE localization was suggested by the increased nuclease sensitivity of NE-associated chromatin. Since increased nuclease accessibility usually correlates with gene expression, these studies suggested that NE-associated chromatin might be enriched for active genes. Since mRNA must be exported through NPCs, it was proposed that perhaps active genes were targeted to the NE in order to facilitate transcript export, a hypothesis known as *gene gating*. Gene gating is particularly appealing in the case of

genes whose transcripts are nonrandomly localized relative to the nucleus: if the corresponding gene was nonrandomly localized to the NE near the site of future message accumulation, then locally increased export through the nearby nuclear pores could explain the ultimate asymmetric transcript localization. The fact that some transcript localization is perturbed in a nuclear lamin mutant might tend to support this model.

Although these studies raised the possibility that active genes might be targeted to the NE, in most cases it has been found that active genes are, in fact, nonrandomly localized to the nuclear interior and not to the NE. As for a role of the NE in transcript localization, a careful study of many pair-rule genes in *Drosophila*, whose transcripts are specifically localized relative to the nucleus, revealed no relation between the position of the gene in the nucleus and the position of transcript accumulation. These studies suggest that gene gating probably does not play any significant role in transcript targeting or export.

5.3 Nuclear Compartmentalization and Gene Expression

Heterochromatin tends to be nonuniformly distributed in cells. In most cell types, the heterochromatin aggregates into a small number of large domains, and when euchromatic genes become silenced by heterochromatic insertions (a phenomenon called *position effect variegation* in *Drosophila*), the genes become localized to these large heterochromatin domains. This relocalization probably plays a causal role: when a euchromatic reporter gene was artificially targeted to the heterochromatin domain in *Drosophila* by flanking chromosome pairing sites, the gene became silenced. Moreover, chromosome rearrangements that impede localization of a gene to the heterochromatin domain have the effect of reducing silencing. Thus, a probable model is that the heterochromatin domain creates a ''bad neighborhood'' for transcription of euchromatic genes, and that when genes are brought into this neighborhood they tend to become silenced.

This model may also explain the ability of certain sequences (known as *insulators*) to protect nearby euchromatic genes from silencing by heterochromatin. The gypsy insulator protects genes from silencing by nearby heterochromatin, and its function requires the Su(hw) and mod(mdg4) proteins. These two proteins localize to the NE, as does the gypsy insulator itself. Su(hw) mutants that prevent insulator function cause the insulator sequence to dissociate from the NE. These results imply that Su(hw) protein tethers insulator sequences to the NE, and more importantly, that possibly this tethering could be critical in insulator function. One way this would work would be to lock genes in place near the NE, preventing them from relocating from their initial position into the silenced heterochromatin compartment.

6 Role of Nuclear Architecture in Chromosome Interactions

6.1 Regulation of Interactions by Constrained Diffusion

Many aspects of DNA metabolism involve interactions between widely separated loci.

For example, recombination frequently involves an interaction between sites on two entirely different chromosomes. Another example is transvection, in which a promoter on one chromosome can drive transcription of a coding region on another chromosome. These interactions do not occur at a distance, but instead require the interacting sites to move into close physical proximity. If the organization of genes in the nucleus is nonrandom, then we can predict that the ability of genes to interact with each other is likewise nonrandom. It is verified experimentally that interactions between different loci during recombination and DNA break repair is highly nonrandom. As an obvious example, corresponding loci on homologous chromosomes will be expected to occupy similar regions of the nucleus. Similarly, nucleolar loci are more likely to interact because they are nonrandomly close together from the outset.

The strong influence that nuclear architecture can have on chromosome interactions can be best seen during the establishment of somatic homolog pairing, which is best known in *Drosophila* but also occurs sporadically in humans and yeast. An analysis of initiation of somatic pairing in *Drosophila* showed that the loci that paired first tended to start out close to each other within the nucleus, while loci that started out far apart tended to pair later. In fact, the pairing could be modeled precisely assuming that chromatin motion was driven by constrained diffusion and taking into account the known nuclear architecture in the *Drosophila* embryo. Thus, as suggested by the studies of Robertsonian translocations, it appears that position within the nucleus plays an important determinative role in interactions between chromosomes.

We can therefore propose a general model: because chromatin diffusion is constrained to a small subregion of the nucleus, only loci whose regions of confinement overlap will be able to interact. Loci that start out far apart will be prevented from interacting, since their regions of confinement do not overlap, so that physical contact is impossible. Thus, the relative positions between loci, as dictated by the nuclear architecture, can play a decisive role in determining which interactions can occur.

6.2 Robertsonian Translocations

Robertsonian translocations, spontaneous reciprocal translocations of whole chromosome arms, provide an illustrative example of the influence that nuclear organization might have on chromosome interactions. The distribution of breakpoints in such Robertsonian translocations is highly nonrandom, such that translocations in which both breakpoints occur on acrocentric chromosomes containing nucleolar organizing regions (NORs) are highly favored. Since cells generally have just a single nucleolus, chromosomes with an NOR will tend to be nonrandomly close in the nucleus, thus biasing the distribution of recombination breakpoints.

6.3 Chromosome Rearrangements in Cancer

Perhaps the most important instance of nuclear architecture influencing chromosome rearrangements occurs in chromosome translocations that lead to leukemia. A translocation between the BCR and ABL loci on chromosomes 22 and 9 gives rise

to a translocation called the Philadelphia chromosome, and the breakpoint encodes a novel fusion protein called BCR-ABL. The majority of patients with chronic myelogenous leukemia (CML) contain this rearrangement in their genomes. Why is this rearrangement so common? FISH measurements show that BCR and ABL loci are in fact nonrandomly close together in the nucleus, which may account for the high frequency of recombination between these two loci. Another rearrangement important for cancer involves the RET and H4 loci. An inversion with breakpoints in RET and H4 is found in many cases of radiation-induced thyroid cancer. As with BCR and ABL, RET and H4 are nonrandomly close together in normal cells, again suggesting that it is the spatial proximity of these loci that allows them to recombine so frequently.

7 Conclusions

Clearly, a more detailed understanding of nuclear architecture is critical for the progress of molecular medicine. Understanding how the specific positioning of genes occurs, and what influence this positioning has on gene expression and recombination, will lead to a clearer understanding of chromosome behavior in interphase. The key is to uncover the molecular players that establish and maintain nuclear architecture.

Keywords

BAC
Bacterial artificial chromosome based cloning vector capable of accommodating large fragments of genomic DNA.

Chromosomal Band
Variation in the staining of DNA due to differential binding of dyes along the length of the chromosome.

Chromosome
A self-replicating genetic structure that contains the cellular DNA representing the linear array of genes.

Chromosome Fragment
A small portion of chromosomal DNA obtained by means of physical excision using microdissection.

Gene Mapping
Determining the relative position of one or more genes on chromosomes.

Karyotype
A photomicrograph of individual chromosomes arranged in a standard format showing the number, size, and shape of each chromosome.

Megabase
One million base pairs of nucleotides.

LCM
Laser-capture microdissection. A devise that delivers laser pulses to dissect tissues or chromosomes. Pulses can be tuned in variable micron diameter.

Metaphase Chromosomes
Condensed chromosomes at metaphase during the cell cycle.

Microarray
A technology that assesses gene expression by arraying PCR-amplified cDNA clones or genes at high density on derivatized glass microscope slides (known as a DNA chip). Relative expression levels are simultaneously determined by specific probe hybridization.

Microdissection
A method to physically cut and collect chromosomal fragments by means of very fine needles and micromanipulators or by a laser microbeam.

Polymerase Chain Reaction(PCR)
A technique by which target DNA sequences may be replicated (amplified) selectively *in vitro*.

Proteomics
The global analysis of expressed proteins in a cell or tissue phenotype in attempt to establish the relationship between the genome sequence, the expressed proteins, and the protein–protein interactions.

YAC
A yeast artificial chromosome based cloning vector capable of accommodating larger pieces of genomic DNA (average insert >100 kb).

This article reviews the pertinent aspects of chromosome structure, microdissection techniques, and methods of microcloning. Recent applications of this technology are discussed. Microdissection is a specialized aspect of cell microsurgery by which one can remove a chromosome fragment from a cell in metaphase. The DNA material thus obtained can be used for molecular cloning experiments. Coupling this technology with *in vitro* DNA amplification using polymerase chain reaction (PCR) and gene-transfer techniques have made possible the performance of biochemical and biological experiments using small amounts of DNA obtained from chromosome fragments. The emerging technology of laser-capture microdissection (LCM) and its potential applications in global gene expression and profiling (proteomics) is also introduced.

1
Chromosome Structure and Organization

DNA is coiled in eukaryotic chromosomes in a hierarchical fashion with several levels, to achieve the highest degree of condensation. Chromosome organization is described in the following orders of DNA folding (from lowest to highest): naked double-stranded DNA, DNA coiled around core nucleosomes, the 30 nm chromatin fiber, the 250 nm chromatin fiber containing DNA loops, helical coiling of the 250 nm chromatin fiber, chromosome bands, and finally chromosome regions. At the first level of DNA folding, linear double-stranded DNA is coiled around a histone core octamer (two copies each of H2A, H2B, H3, and H4). The DNA undergoes two left-handed superhelical turns around the core histone octamer to form a *nucleosome*. Adjacent nucleosomes are connected by ''linker'' DNA, which may be 8 to 114 bp long in different eukaryotic species. Nucleosomes are folded in the form of a simple solenoid structure that generates a 30 nm *chromatin fiber*. There are six nucleosomes per turn (approximately 1.2 kb DNA). In both the interphase and metaphase nucleus, the 30 nm fiber is folded in a loop structure. The chromatin loops contain between 5 and 100 kb of DNA. One model predicts radial arrays of ten 30 kb loops yielding an array of about 300 kb – that is, approximately 250 nm in width. The chromatin loops are anchored to a nonhistone protein structure that is referred to as the *nuclear matrix* or the *chromosome scaffold*. The metaphase chromosome scaffold is positioned along the central axis of the chromatid. *Topoisomerase II,* a major component of the scaffold structure, is localized along the length of the chromatid. Topoisomerase II appears to behave as a ''loop fastener'' in addition to its catalytic function during replication and transcription. DNA segments that interact with the scaffold (scaffold-associated regions: SAR) or with the nuclear matrix (matrix-associated regions: MAR) are 0.6 to 1.0 kb in length and are presumed to form the base of the loop structure. The metaphase scaffol can be visualized microscopically by using treatments that partially deplete chromosomes of histones. Under these conditions, the scaffold has been observed to undergo a helical coiling resulting in a further ninefold compaction of the chromosome in metaphase. This structural feature accounts for the zigzag appearance of chromatids and probably represents partially uncoiled structures.

During interphase, the extended, uncoiled chromosome scaffold structure yields chromatids approximately 250 nm in width, whereas the condensed, coiled scaffold in metaphase yields a width of 700 nm. After metaphase, there is selective decondensation (uncoiling) of euchromatic chromosome regions. Specific mammalian chromosomes can be identified by the pattern of transverse bands produced by a fluorescent dye or by Giemsa stain. Chromosome bands have become topographical landmarks used to map genes, inherited traits, and chromosome structural abnormalities, and as reference points for large-scale genomic sequencing projects. Chromosome bands represent not only structural but also functional compartmentalization of the genome.

The number of visible bands (e.g. Giemsa dark bands or ''dark G-bands'') depends on the exact stage in the cell cycle at which chromosomes are examined. Chromosomes in midprophase will yield approximately 2000 bands in a human karyotype. Later, in early metaphase, when chromosomes are condensed, only 450 to 800 G-bands will be visible. An

average dark G-band in prophase contains approximately 1.5 Mb of DNA, whereas an average-sized light G-band in metaphase contains 10 to 30 Mb. Therefore, condensed metaphase bands are more heterogeneous (i.e. composed of multiple band types) than those found in midprophase. Each metaphase G-band contains about 15 to 50 fg of DNA. Chromosome bands can be visualized using other fluorochromes. Quinacrine mustard and its derivatives have specificity for chromatin regions that are rich in deoxyadenine (dA) and deoxythymidine (dT). Quinacrine staining produces a banding pattern (Q-bands) that is different from that due to fluorochromes with affinity for deoxycytidine (dC) and deoxyguanidine (dG) residues (e.g. chromomycin A3 and mitramycin). Treatment of fixed chromosomes with trypsin followed by staining with Giemsa (GTG banding) yields dark (G) and light (reverse or R) bands. R-bands usually correlate with bright bands detected with quinacrine (Q-bands). Giemsa staining of human chromosomes after heat treatment results in preferential staining of centromeric and paracentromeric regions, as well as regions of chromosomes 1, 9, and 16 and the telomere of the Y chromosome; these patterns are referred to as *C-bands*. C-bands are regions of constitutive heterochromatin and remain condensed throughout the cell cycle, except for a short period of time during DNA replication.

The structural compartmentalization of chromosomes into transverse bands obtained with Giemsa and fluorescent dyes can also be seen by treating chromosome spreads with the restriction endonuclease *Hae*III, as well as with *in situ* hybridization using repeat-sequence DNA probes. Long interspersed element (LINE) repeats are found predominantly in G-bands, whereas short interspersed element (SINE) repeats or *Alu* sequences are found in R-bands. The differing base composition of these two repeat DNA groups accounts for the higher GC content of R-bands in contrast to higher AT content of G-bands. C bands do not contain SINEs or LINEs but are made of highly repetitive sequences called *satellite DNA sequences*.

The structural organization of chromosome bands has profound implications for the regulation of gene expression. Most housekeeping genes and the majority of tissue-specific genes are found in R-bands. In this regard, clustering of nonmethylated CpG dinucleotides (HTF islands), which is usually found 5′ to ''housekeeping'' genes, appears to be restricted to R-bands. The staining techniques likely to generate bands for microdissection are summarized in a number of student cytogenetic manuals. Other chromosomal structural regions such as the centromeres and telomeres are also very amenable to microdissection. The primary constriction in mammalian chromosomes is called the *centromere*, and its location is useful in the preliminary grouping of human chromosomes. The centromere is composed of constitutively condensed chromatin, α-satellite DNA, composed of multiple copies of highly diverging basic repeat units of approximately 171 bp. Tandem repeats of α-satellite DNA are further organized into micro repeat units ranging in length from 0.5 to 10 Mb. Human chromosomes can be distinguished from one another by their divergent α-satellite sequences.

The chromosome ends, or *telomeres*, are specialized structures that are essential for the maintenance of chromosome integrity. Telomeres are likely to be important in the spatial positioning of the chromosomes in the nucleus as well. The primary structure of telomeres is a conserved G/C-rich repeat

unit of the general formula D (T/A_{1-4} dG_{1-8}). The terminal repeat number varies considerably in different species, from a few hundred base pairs in ciliates to 10 kb in humans, and up to 150 kb in mice. This review of chromosome structure was confined to essential background, and more detailed discussion of this subject can be found elsewhere.

2 Preparation of Chromosomes for Microdissection

Methods of preparing chromosomes and chromosome bands have been empirically developed by cytogeneticists over the last four decades. These methods, however, must be modified when chromosomes are to undergo microdissection. Conventional banding and staining techniques result in degradation of chromosomal DNA and hence render the DNA unsuitable for biochemical and biological studies. In fact, it is evident that improvement in GTG banding is associated with increased DNA degradation. A number of factors contribute to DNA breakdown during the preparation of chromosome spreads. DNA appears to be more unstable (i.e. susceptible to denaturation and DNAse digestion) in condensed metaphase chromatin than it is in interphase chromatin. Furthermore, at each step in the preparation of metaphase chromosomes – that is, hypotonic swelling, fixing, and ''aging'' – DNA degradation is facilitated.

Chromosome fixation and aging contribute most significantly to chromosomal DNA degradation. Therefore, it is essential in microdissection experiments to consider chromosomes as units of linear DNA rather than cytogenetic structures.

Several critical aspects of chromosome preparation for microdissection experiments are worth mentioning. These include the enrichment of preparations for metaphase spreads, hypotonic treatment, chromosome fixation, aging, staining, and storage of chromosomal DNA. When planning for microdissection, it is ideal to have as many metaphase spreads as possible on one coverslip. Only a fraction of the spreads are amenable to dissection because of the poor extension of chromosomes in some spreads, overlapping chromosomes, or disadvantageous orientation of the chromosome of interest. The number of metaphase spreads may be increased by synchronization in the cell cycle to capture the maximum number of cells in mitosis. In most instances, adequate numbers of mitotic cells can be obtained from short- or long-term monolayer cultures without drug synchronization by plating cells sparsely and harvesting mitotic cells when cells are in a log phase of growth. If necessary, the thymidine ''block'' and ''release'' method may be used. The use of synchronizing agents such as antimetabolites (e.g. methotrexate), cytotoxic drugs (e.g. actinomycin D), or other chemicals capable of inducing DNA damage is not advised.

2.1 Aspects of Preparing Mammalian Chromosomes

2.1.1 Sources of DNA

Several sources can be used to prepare chromosomal DNA for microdissection. If whole-blood microculture is used, metaphase spreads are prepared from peripheral blood T lymphocytes as follows. Venous blood is drawn into a heparinized tube or into a syringe containing 0.1 mL of heparin stock solution (5000 IU mL^{-1}).

A few drops of heparinized blood are mixed with 5 mL of prewarmed chromosome 4A medium or growth medium containing 0.2 mL of phytohemagglutinin solution in sterile polypropylene tubes. Cultures are set up in duplicate and placed in an incubator at 37 °C for 72 h. A stock solution of colcemid (diacetylmethylcolchicine) is added to each tube to a final concentration of 0.05 μg mL^{-1} and incubated for an additional 30 min. The cell pellet is prepared by centrifugation at 800 *g* for 10 min and resuspended in warm (37 °C) 5 mL hypotonic solution (0.075 M KCl) and incubated at 37 °C for 10 min. The cell pellet is prepared again by centrifugation at 800 *g* and is resuspended in 5 mL of cold 3 : 1 methanol–acetic acid fixative on ice. Cells are dropped onto large, (35 mm × 50 mm) cold, wet coverslips using a Pasteur pipette. Coverslips are examined first on a phase microscope to determine whether the spreads are at the correct density. The coverslips are kept at −70 °C in ethanol for a few hours or until use. Immediately before use, coverslips are immersed in ice-cold distilled water. If monolayer tissue culture cells are used to prepare chromosomes, the cells are seeded at low density onto plastic petri dishes for 24 h; then the medium is removed and replaced with fresh medium. Colcemid solution is added 48 to 72 h later and cultures are incubated for 10 min to 1 h at 37 °C in a 5% CO_2 incubator. Cells are removed from the culture plate or flask and processed as described for lymphocytes.

Among the numerous effective mitotic spindle inhibitors, colcemid is particularly useful, as it arrests cells at the M/G2 interphase. Since chromosomes become more condensed and shorter at the end of metaphase, short incubation times with colcemid (10–60 min) tend to yield more extended chromosomes. This is preferable, particularly when one is dissecting small chromosomes or attempting to dissect minor bands. The use of agents that promote chromosome extension and enhance DNA nicking (e.g. ethidium bromide) should be avoided.

2.1.2 Hypotonic Solution

The hypotonic solution swells the nucleus and cytoplasm, breaks intrachromosomal connections, and allows a better separation of chromosomes when the cells are smashed on a coverslip. Hypotonic treatment of cells results in degradation of DNA from chromosome spreads. Therefore, the shortest length of exposure to hypotonic solution is preferable. Lymphocyte cultures usually can be treated for 10 min at 37 °C to produce adequate spreads, whereas monolayer cell lines are usually treated for 30 min at 37 °C. Prolonged hypotonic treatment results in cell lysis and dispersion of chromosomes over a large area. Less than optimum hypotonic treatment results in tightly packed metaphase spreads that may not be suitable for microdissection.

2.1.3 Chromosome Fixation

Chromosome fixation serves to arrest chromosomes at a specific stage in the cell cycle with little distortion of morphological detail. Optimum fixation also rids the spreads of cytoplasmic debris. The most commonly used fixative is a mixture of methanol and acetic acid, at a ratio of 3 : 1 or higher. Acetic acid, which has excellent penetrability, will precipitate nucleoprotein, extract considerable amounts of chromosomal proteins, and remove cytoplasmic constituents from metaphase spreads. Mixtures of acetic acid and methanol produce minimal swelling or condensation of chromosomes. Acetic

acid fixation for chromosome microdissection studies has one major adverse effect: it causes depurination and nicking of DNA. Depurinated DNA is more susceptible to enzymatic digestion as well as to the DNA degradation associated with chromosome aging. Therefore, a number of precautions and modifications of standard fixation protocols should be observed. Since acid depurination is a hydration reaction, acetic acid and methanol should be free of water. Reagents should be aliquoted into small bottles and kept well sealed. All steps in chromosome fixation and spreading should be done at 0 to 4 °C. Care should be taken to avoid prolonged exposure of chromosomes to fixative. Depending on the cell type, cells may be kept in fixative for a few seconds to 10 min before spreads are dropped onto coverslips.

2.1.4 Aging

Once metaphase spreads have been fixed and dropped onto coverslips, the chromosomes must be aged to obtain optimum GTG banding. Aging is accomplished by keeping chromosome spreads at room temperature for 3 to 5 days or at 56 °C overnight. The precise physicochemical basis for the aging of chromosomes is unknown, but it is evident that chromosomal DNA that has become depurinated by acid fixation grows increasingly single stranded and is degraded during the aging process. Therefore, when possible, it is preferable to microdissect fresh, uniformly stained (solid staining) or unstained chromosomes. This procedure is certainly applicable to the microdissection of telomeric or centromeric regions of chromosomes, which are readily recognizable by size and morphology. Similarly, the microdissection of marker chromosomes and double minutes can be performed with unstained material.

2.1.5 GTG Banding for Chromosome Microdissection

GTG banding of metaphase chromosomes is the most commonly used technique when chromosomes must be stained for identification of a specific chromosome or chromosome region. Coverslips are removed from ethanol and are placed in a sterile Coplin jar containing pH 6.8 buffer at room temperature. The coverslips are immediately removed from the buffer and are placed in sterile 0.5% trypsin/EDTA solution (in Hanks buffered salt solution), and incubated at room temperature for 1 to 3 min. If solid staining is desired, the trypsin/EDTA step is omitted. The coverslips are washed for 1 s in pH 6.8 buffer and then placed directly into Giemsa stain. Staining may take 15 to 90 s. The coverslips are washed twice in pH 6.8 buffer and air-dried. The optimum time for trypsin treatment and staining should be determined experimentally. After a coverslip has been air-dried, DNA will begin aging. Therefore, to obtain high-quality DNA, it is recommended that microdissection be performed immediately after staining. Also, to avoid contaminating slides with foreign DNA, the staining procedure should be performed in a biological containment hood. Sumner has reviewed chromosome banding.

2.2 Preparation of Dipteran Chromosomes

Drosophila chromosomes may be prepared from dipteran salivary gland for microdissection. Salivary glands are dissected in insect Ringer's solution and are spread on a siliconized coverslip in a drop of 45% acetic acid. The tissue is squashed between two siliconized coverslips. The coverslips are then held in place with forceps and quick-frozen in liquid nitrogen.

They are separated by flipping them apart with a razor blade. The coverslip containing the squash preparation is placed in three successive ethanol washes (70%, 95%, absolute) for 1 min and either kept in ethanol or air-dried; it may then be kept in a moisture-free, airtight box until use. Conditions of aging, fixing, and storage described for mammalian chromosomes should be used when preparing *Drosophila* chromosomes.

3
Methods of Chromosome Microdissection

The methods used in microdissection and isolation of chromosome fragments are an extension of the methods and instrumentation originally used for cell microsurgery. Many of the cutting needles and nanoliter volume pipettes were described nearly a half-century ago by De Fonbrune. De Fonbrune also described the tools for fashioning micropipettes, such as micromanipulators and the microforge. Edström and his colleagues later reported the first definitive chromosome microdissection experiment using chromosome spreads in an oil chamber. The oil chamber was placed on an upright microscope and microdissections and DNA extractions were performed using curved micropipette tips and nanoliter volumes. Subsequently, microcloning experiments were done in nanoliter aqueous drops under oil. While this was an effective method, particularly in skilled hands, Hagag and Viola and others found the use of an inverted microscope and straight needles to be technically easier and more generally applicable. Hagag and Viola described and improved the method by utilizing an inverted microscope equipped with a high-magnification system. Other groups have described microscopes equipped with a laser microbeam for chromosome microdissection. The laser microbeam has evolved into a new technology known as *laser-capture microdissection* (LCM). LCM allows the collection of a minute amount of DNA and RNA from a pure cell population in a heterocomplex tissue. A brief account of each of these methods is described below.

3.1
Equipment

The equipment for chromosome microdissection includes a microscope, a pair of micromanipulators, a micropipette puller, a microinjector, micropipette holders, and glass tubing to make microdissection needles and nanoliter transfer pipettes. A microforge and a micropipette grinder are optional for fashioning specialized micropipettes. An ideal microscope (upright or inverted) should have the following features: first, a high-intensity light source with a short and efficient light path; second, a high numerical aperture phase and fluorescence optics. The condenser should permit a sufficient working distance (10–20 mm) and should allow easy interchange between the various optics during manipulations. Third, several specimen holders that permit easy access to chromosomes on the slide are required. These holders should be easily attachable to the stage and capable of rotating freely to align chromosomes with microdissection pipettes. Other accessories (camera ports, video ports, etc.) must not interfere with accessibility to the micromanipulators and micropipettes. At least one micromanipulator is required for microdissection of chromosomes. A second manipulator may be handy for the simultaneous manipulation of the chromosomal fragments after

dissection (e.g. fragment collection, transfer to aqueous drops). Three-dimensional mechanical or hydraulic micromanipulators are best suited for this application. A hydraulic drive system with three-axis motion and single-direction angular movement controls ensures smooth, precise, vibration-free movement during operation. Most micromanipulators are equipped with a fine drive joystick to reduce hand movement during dissection, separation, and collection of fragments.

Microdissection needles or micropipettes are produced from borosilicate capillary tubes (1 mm o.d., 0.65 mm i.d.) using a two-stage micropipette puller (e.g. Narshige PP83). A micropipette puller helps prepare needles consistently with a specifically programed tip diameter. Dissecting needles and volumetric micropipettes are drawn to a long taper with a tip diameter of approximately 0.5 µm. The pipette ends must be flexible enough to permit the tip of the needle to accept pressure without breaking. This balance between needle flexibility and sharpness of the tip must be determined empirically by the investigator. The diameter of the micropipette can be estimated using a microscope and a microgrid (e.g. Graticules Ltd., England). The dissecting needle is fitted into a microinjector (e.g. Eppendorf) holder or a microsyringe. The micropipettes are connected with Tygon or Teflon tubing to the injector. The micropipette, tubing, and syringe may be filled with silicone fluid (which is inert for most biochemical procedures), to provide a closed injection–suction system. Chromosome fragments are cut and pooled into an aqueous drop of 1 to 2 mL. The collection droplet is placed under a small volume of silicone oil on a depression slide or a moist chamber next to the dissection slide.

3.2 Methods

3.2.1 Oil Chamber Method

Microdissection using the oil chamber method was first described for dissecting and microcloning of polytene chromosomes and has been applied since to the dissection of mouse and human metaphase chromosomes. The oil chamber consists of a one-piece glass slide that measures $70 \times 35 \times 6\ mm^3$ with a rectangular groove 25 mm wide and 3 mm deep. Chromosome spreads are prepared on $12 \times 30 \times 0.17\ mm^3$ coverslips. Glass chambers and coverslips are washed in hydrochloric acid and distilled water before use. The coverglass is placed on the groove (chromosome spreads side down). All microdissection and microcloning operations are performed on the lower surface of the coverslips using various dissection needles and volumetric pipettes. The space between the coverslips and the bottom of the chamber is filled with liquid paraffin. The liquid paraffin used in the oil chamber also contains phenol–chloroform droplets and buffers to be used for extraction, solubilization, and restriction enzyme digestions and subsequent microcloning. In this method, investigators used an upright phase contrast microscope equipped with a long working distance condenser to view through the thick oil chamber. Focusing was done by moving the stage. Microdissection was performed under a high-power dry objective (e.g. 40×). All other manipulations, such as micropipetting, transfer of DNA fragments to aqueous droplets, and DNA extractions, were done with low-power objectives (10 and 20×). Figure 1 represents the oil chamber apparatus and microcloning steps.

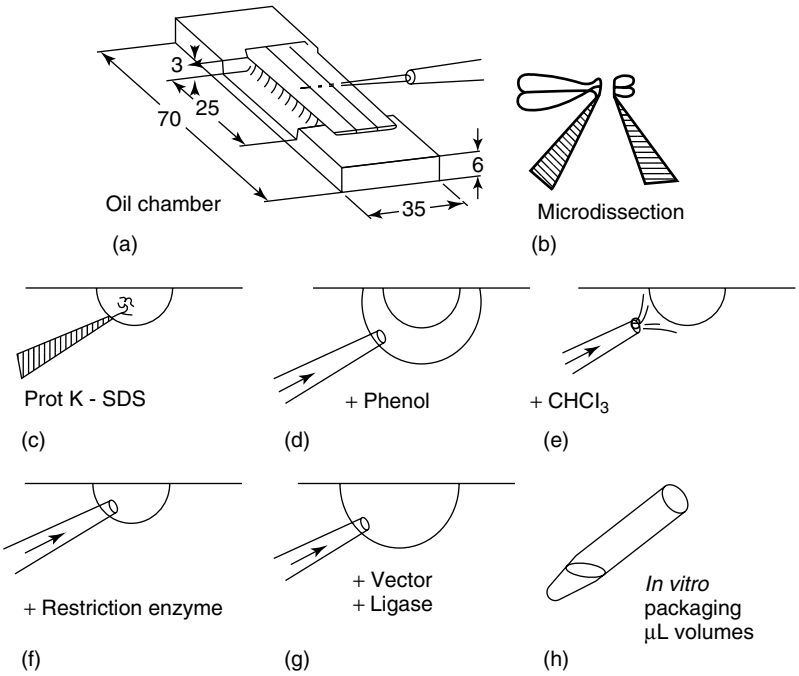

Fig. 1 Oil chamber microdissection apparatus: (a) dimensions of the oil chamber (mm) and (b)–(h) steps of microcloning operations.

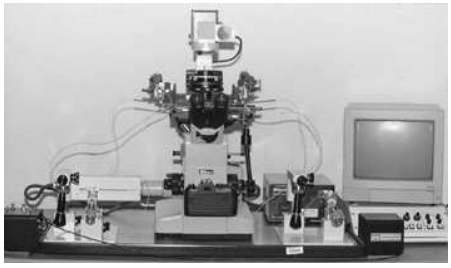
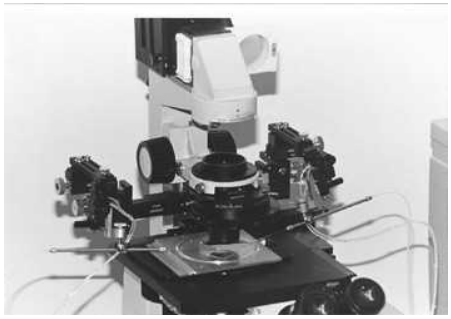
3.2.2 **Videomicroscope Method**

We have described a chromosome workstation that can be used for microdissection and *in situ* hybridization experiments (Fig. 2a). The station features an inverted microscope equipped with a fixed stage, a low-level light video camera, and a video monitor. A 12 V, 100 W halogen lamp and a high-focal length phase-contrast condenser were added to enhance illumination and obtain a better resolution of chromosomal GTG bands. In addition, a new microscope stage was designed, featuring a mechanical stage with *XY* coordinates graduation and a circular rotating stage in the center (Fig. 2b). The circular stage accommodates the holders for the dissection and collection slides. For easy relocation of a specific chromosomal spread, the center stage is also graduated 360°. The circular stage offers the advantage of rapidly positioning target chromosomes perpendicular to the dissecting needle tip regardless of their orientation in the spread on the slide. Also, the stage accepts large coverslips (35 mm × 50 mm), thus maximizing the number of spreads on a slide as well as the number of chromosome fragments collected per session.

Video cameras have an inherent magnification factor that may range from 10× to 200×. For example, the video camera series QX-104 (VSP Inc.) and the charge-coupled device (CCD) video camera CCD-72 (Dage Corp.) have an intrinsic magnification factor of 40×. When coupled with a microscope using a 40 or 63× objective, we were able to achieve magnification of metaphase chromosomes on the



(a)



(b)

Fig. 2 (a) Videomicroscope microdissection apparatus. This system is composed of the Nikon Diaphot microscope, CCD 72 video camera, high-resolution display monitor, two micromanipulators, two microsyringes, and the rotating microdissection/microinjection stage. The entire system is placed on a tabletop vibration-free system. (b) Close-up showing the rotating stage and the micromanipulators mounted on the microscope stage.

video monitor by a factor of roughly 1600 to 2500×. Moreover, with the available high-resolution TV/video camera microscope couplers (e.g. 2× HR200 series coupler), an additional 0.5 to 2× magnification factor can be added. When a CCD camera with a 2× coupler was used, the magnification was further raised to about 3200 to 5000× using 40 and 63× dry objective lenses respectively. The CCD cameras are better for this application because they are ultrasensitive to low light and their parafocality and focusing can be adjusted electronically. The resulting image is displayed on a VGA monitor or an equivalent color monitor. The image on the monitor can be further improved by the appropriate choice of microscope TV/video coupler, interference contrast filter, lens, and resolution of the display monitor. The videomicroscope is placed on a tabletop isolation platform (e.g. Vibraplan, Kinetics Systems, Inc.). These platforms are passive air-mount templates that float freely when inflated to the load-supporting pressure, thus minimizing vibrations transmitted to the microscope and accessories. Microdissection is performed while observing the chromosome on the video monitor. In this manner, it is possible to visualize secondary and minor bands that are below microscope limits of resolution for a light microscope. Moreover, the system's real-time design enables one to observe on the monitor the various micromanipulations, which may serve as a useful teaching tool as well. Using the videomicroscope, it is possible to cut chromosome fragments less than 0.5 μm long (i.e. a single band of a human chromosome). The precision of the dissection of a specific chromosomal band is substantially improved by the two- to threefold enhanced magnification. For example, a human chromosome 1 is

about 7 μm long and measures roughly 2.8 mm long on an objective lens of a light microscope at 40× magnification. With the videomicroscope, it would measure 2.24 cm on the display monitor. Thus, an average GTG band of 0.4 μm will measure about 2 mm using a phase or light microscope and it is relatively difficult to resolve bands corresponding to 10 to 30 Mb of chromosomal DNA. By using the videomicroscope and a fine cutting needle, fragments containing as little as 10 Mb (about 0.4 μm) can be readily resolved.

The videomicroscope microdissection method offers a number of other advantages. The use of an inverted microscope permits convenient working distance for performing the micromanipulations. The system overcomes light- and contrast-limited situations by means of the picture enhancement provided by the video camera and monitor.

Furthermore, microdissection in air makes it easier to see the needle when dissecting chromosomes.

3.2.3 Laser Microbeam Method

The laser microbeam microdissection of Monajembashi et al. is based on the principle that at high photon densities, light can liquefy, evaporate, or break down optically active biological material. Even chemical bonds are cleaved when a biological material is heated locally to a few thousand degrees for nanoseconds to microseconds. The laser microbeam apparatus consists of an excimer laser as a primary source of laser light (e.g. Lambda Physik EMG 103 MSC). An additional dye laser (Lambda Physik FL 2002) is utilized to improve the beam quality and select a specific wavelength. A circular disk system of concentric rings is used to deliver high-pulse energies at a repetition rate of about 10 Hz. Energy densities of more than 10^{14} W/cm^2 can be achieved by selecting a ring with a radial distance that corresponds to the wavelength in use. The pulses are directed into an inverted microscope via the fluorescence illumination path and are focused through the objective into the object plane. The pulses of the laser, 20 ns in length, are directed into a microscope using optics similar to that of a fluorescence microscope (e.g. Ultrafluar 100, which has a numerical aperture of 0.85 by Zeiss).

The microbeam laser system provides pulse energies between 1 and 10 mJ at a wide range of wavelengths (320–800 nm) that is optimum for several dyes and is particularly suitable for working with ultraviolet light. A UV wavelength is appropriate for microdissection of chromosomal DNA because the damaging effect of the laser is limited to an area nanometers away from the cutting region. Therefore, the secondary damage to DNA is negligible. Proponents of this method indicate that DNA situated in chromosome slices dissected by this procedure using UV laser above 300 nm will retain its biological integrity and is highly suitable for subsequent microcloning procedures. Damage of DNA by stray light is expected only for wavelengths well below 300 nm. The principle of this technique has recently been applied to the microdissection and cloning of both human chromosome fragments and *Drosophila* polytene chromosome bands and several other species.

Chromosomes of human lymphocytes were prepared by standard procedures on cover glass, treated by the ring system with a single laser pulse. Each slice was, on average, 0.5 μm thick. The slices were taken up by a microdrop and used as is for cloning experiments. A schematic of the laser microbeam microscope is shown in Fig. 3.

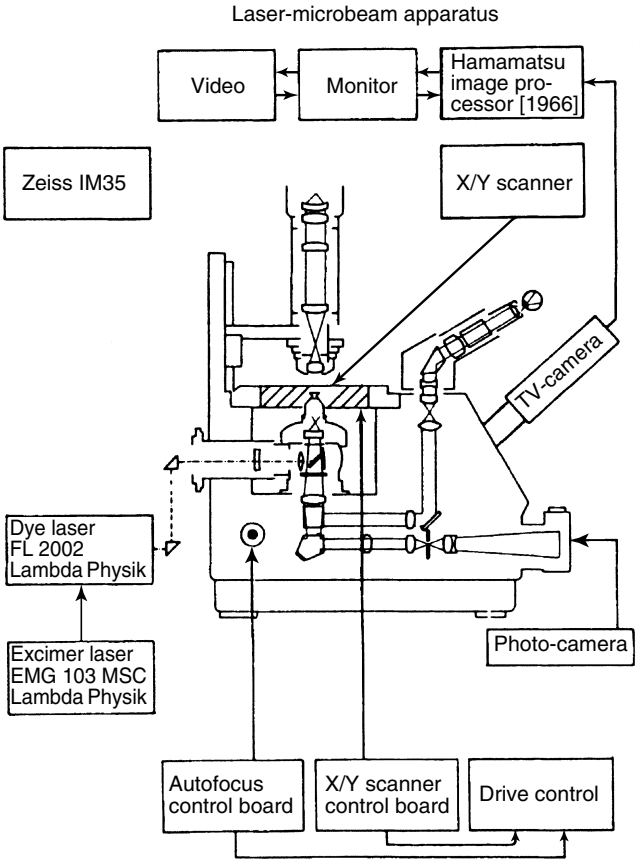


Fig. 3 Diagram of the laser-microbeam microdissection apparatus. The microinstruments necessary for fragment collection and manipulation (not depicted) are essentially the same as described earlier.

3.3

Dissection and Collection of Chromosome Fragments by the Videomicroscopy Method

Approximately two days before microdissection, cultures are initiated to prepare high-mitotic index cells according to standard procedures. Metaphase spreads are prepared a few hours before microdissection and stored in ethanol. Chromosomes are GTG band–stained immediately before the scheduled microdissection. Volumetric micropipettes (i.d. $\simeq$1–2 µm) and straight microdissection needles (o.d. = 0.2–0.5 µm) are prepared at precalibrated settings on a micropipette puller, filled with paraffin oil, and mounted on the appropriate holders. For chromosomal DNA collection, 200 µL of filter-sterilized paraffin or silicone oil is placed on a depression slide or moist chamber near the dissection slide. Similarly, nanoliter drops of proteinase K/SDS and Tris-HCl solutions are placed under oil using volumetric pipettes. Also, several 1 to 2 mL drops of aqueous Tris-HCl/EDTA buffer are placed adjacent

to the proteinase K drop using another volumetric pipette. The aqueous droplets will be used later for washing and solubilizing extracted DNA. For easy manipulation, all these steps should be performed at low magnification (10×). Coverslips containing the metaphase spreads are secured into the customized slide holder, spreads side up, and mounted onto the rotating stage. Usable spread(s) are identified and marked at 10× magnification for easy orientation of the chromosome of interest. The dissecting needle is placed within a few micrometers of the chromosome of interest in the metaphase spread and at 10× magnification. The system is switched to high magnification (40–60×) and video display (3200–5000×). After the desired chromosome has been identified, the GTG band to be dissected is approached at an angle of about 30 to 45° and the dissection needle is brought up into the field of the spread. Dissections are preferably performed in cells with well-spread chromosomes and when the chromosome of interest is located in the periphery of the metaphase spread. This precaution minimizes cross-contamination with other chromosomal material.

Microdissection is performed with the aid of the micromanipulator by moving the micropipette tip back and forth across the chromosome band of interest. Under these conditions, the chromosomes are readily cut across, and the dissected region is detached from the slide. Each dissection leaves a clear zone in the surrounding cytoplasm, thus allowing easy and reliable verification of the dissected chromosomes. Fragments that are not identifiable are discarded. The selected band is scraped off the slide, and the fragment is pushed to the side with a micropipette. A drop of oil is expelled from the micropipette to cover the fragment and provide a closed system during suction and collection of the fragment. The fragment is secured to the tip of the micropipette by applying suction and a holding pressure that is maintained during fragment transfer. The microscope is then switched to low magnification and the depression slide (containing DNA collection and extraction drops) is brought into the field of view. The micropipette is gently introduced into the oil drop containing the aqueous droplets, while the holding pressure is maintained. The fragment is expelled into the droplet containing proteinase K/SDS solution by reversing the micrometer into the injection mode. The fragment should be visible in the drop at this point. This process is repeated until a sufficient number of fragments have been collected. A schematic representation of the sequence of these steps appears in Fig. 4. An example of microdissection of human chromosome 3 at bands 3p13, 3p14, 3p21, and 3q21 using the videomicroscopy method is illustrated in Fig. 5. The time required to microdissect a specific chromosome region depends on the quality and number of metaphase spreads on the coverslip. With some experience, 10 to 15 fragments can be dissected per hour. Approximately 30 to 100 fragments are sufficient for cloning experiments.

4
Methods of Cloning and Analysis of Microdissected DNA

4.1
Cloning Methods

The first experiments to successfully generate recombinant genomic DNA clones directly from microdissected eukaryotic chromosome fragments were performed in the early 1980s by Jan-Erik Edström and

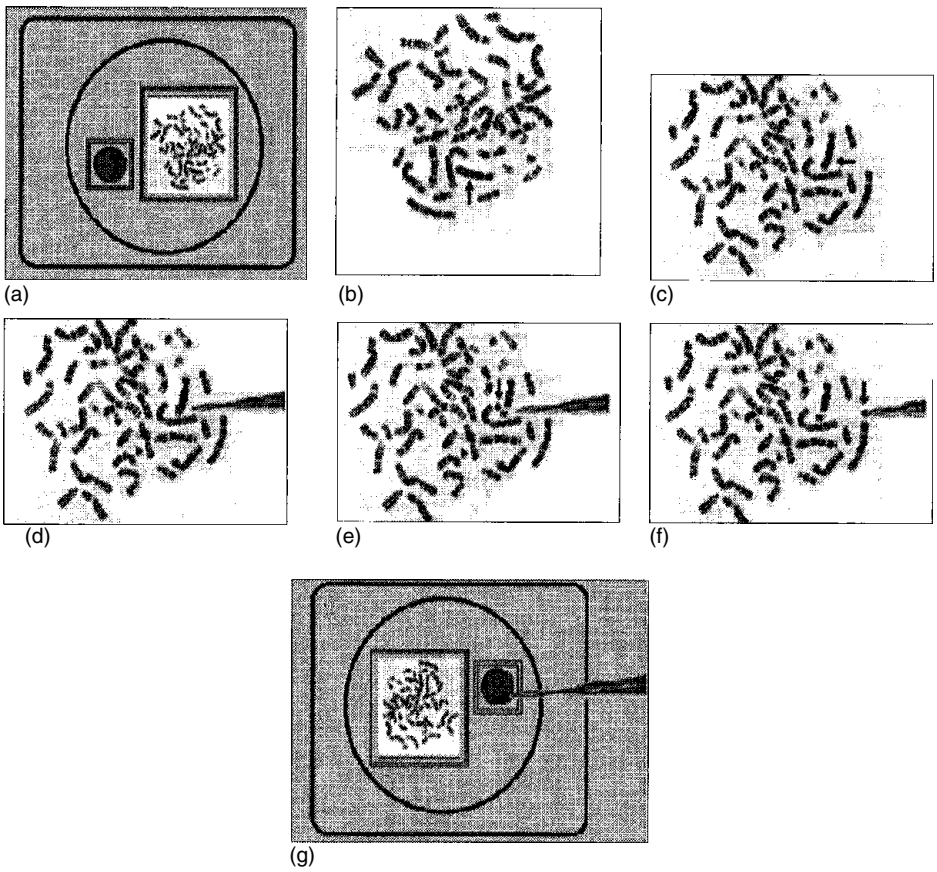

Fig. 4 Sequential steps in chromosome microdissection. (a) Locate a chromosome spread on the dissection slide at 10× magnification, (b) switch to higher magnification to identify the target chromosome for microdissection, (c) rotate the slide to orient the target chromosome perpendicular to the dissection micropipette, (d) lower the dissection micropipette and position the tip proximal to the target chromosomal band (e) cut the chromosomal fragment by scraping across the band in one forward motion, (f) apply suction to the pipette to collect and secure the fragment to the tip of the micropipette, (g) lift the micropipette slowly; rotate the stage to bring the depression slide into the field of view. Lower the pipette, while holding suction, into the aqueous drop under the oil. Eject the fragment into the drop by switching to injection mode.

his colleagues at the European Molecular Biology Laboratory in Heidelberg. The methodology was an outgrowth of the microchemistry work that Edström had developed in the 1960s. During the next twenty years, new technologies emerged and facilitated both the performance of precise chromosome microdissection and the efficiency of cloning chromosomal DNA. A major contribution to these advances was the introduction of PCR technology. PCR permits the amplification of minute quantities of template DNA and generates a product in quantities sufficient for genetic and molecular analysis. Procedures for preparing

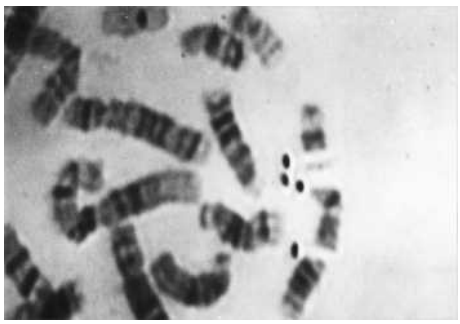

Fig. 5 Example of fragments microdissected from human chromosomes 3 using videomicroscopy. Magnification is 3200× on the display monitor. The fragments cut represent from top to bottom bands 3p21, 3p14, 3p13, and 3q21. Each fragment measures approximately 0.5 µm and contains 10–15 Mbp.

metaphase chromosomes were modified to minimize DNA degradation as reviewed earlier. When care is taken to avoid prolonged acid fixation, microcloning yields recombinant clones with relatively larger DNA inserts. Finally, methods such as videomicroscopy were incorporated to provide higher magnification and resolution of minor chromosome bands.

To date, three distinct approaches can be described for generating recombinant DNA from microdissected chromosomal fragments. In the first and earlier method, DNA was extracted from chromosome fragments in a nanoliter aqueous drop and digested with *Eco*RI restriction enzyme, whereupon the digestion products were directly cloned into a λ-phage vector (this method is often called *microcloning*). The second method is an extension of the first and utilizes PCR. Microdissected DNA is first digested with a restriction enzyme; then, digested DNA is enzymatically ligated either to a linearized plasmid vector or to oligonucleotide linker primers. The cloned inserts are then amplified by PCR using vector-specific primers or the linker primers. This method generates a large number of recombinant clones (usually ≥20 000). DNA from a number of human chromosome bands of considerable clinical interest has been cloned in this way, as discussed in Sect. 4.2. The third method involves the direct PCR amplification of chromosomal DNA using carefully designed oligonucleotide primer sequences that are often termed *universal* or random primers, and more recently using degenerate oligonucleotide primers (DOP-PCR). The universal primers method is based on *Alu* repeat sequences that are naturally present in the genome. The prerequisite of using universal or repeat-sequence primers is that they occur frequently in the genome being studied. The PCR product is then used to probe a more complete recombinant library (cDNA or genomic). The library chosen for screening should contain clones with large inserts [e.g. cosmid, bacterial/yeast artificial chromosome (BAC/YAC) clones]. Hence if a PCR reaction is symmetrical and unbiased, a more complete chromosomal region–specific library can be generated by using the PCR product as a probe. Since our focus is microdissection and microcloning, a more detailed account of these methods is given in Sect. 4.2, with emphasis on the role of PCR and fluorescent *in situ* hybridization (FISH).

4.1.1 **Microcloning**

To initiate the direct cloning of microdissected chromosomal DNA, the DNA was extracted, first with phenol–chloroform, then with proteinase K, and then digested

with restriction enzyme, *Eco*RI. The smaller fragments generated (estimated to be 3–4 kb) were ligated to a λ-phage vector molecule, a reaction that is not dependent on large quantities of insert DNA and thus could be applied to microcloning. The biochemical steps necessary for cloning (phenol–chloroform extraction, restriction enzyme digestion, ligation to cleaved vector) were performed in aqueous drops under oil. The small quantity of recombinant DNA was then added to the packaging mixture and the recombinant phages were replicated in *E. coli*. Using this technique (microdissection and microcloning), genomic clones were obtained from *Drosophila melanogaster* polytene chromosomes, *D. hydei* lampbrush DNA loops, and mouse and human metaphase chromosomes. In these studies, the generation of multiple clones from specific genetic regions has expedited the identification and isolation of a number of important genes (e.g. the t complex in mice and the Kruppel gene in *Drosophila*). The microcloning method requires a large number of fragments (≥100) to provide sufficient starting material for cloning. However, the library of recombinant clones generated with this method usually contains DNA inserts (≤1 kb) that represent only a small fraction (<5%) of the total DNA sequences in the microdissected region.

In addition to low cloning efficiency, the microcloning method has a number of other problems. The use of a phage DNA vector often results in self-religation of phage DNA and the presence of spontaneous phage mutants (false positives). This problem can be minimized by increasing the ratio of insert to cloning vector and by using highly purified phage vectors. Reducing the initial ligation reaction volume to a few nanoliters would increase the cloning efficiency.

To increase the number of recombinant DNA clones, it is necessary to monitor carefully conditions that promote DNA degradation (e.g. excessive acid fixation of chromosomes during preparation of spreads, chromosome aging on slides before staining). Chromosomes should be prepared immediately before microdissection. All slides containing chromosome spreads, handling pipettes, and solutions must be thoroughly cleaned and sterilized. Slides should be examined for the presence of contaminating microorganisms before use.

4.1.2 Linker Adapter with PCR Amplification

In the second method that involves ligation of microdissected chromosomal DNA with a plasmid vector or a linker adapter and PCR amplification, the chromosomal DNA is first extracted with phenol–chloroform and digested with proteinase K in nanoliter drops. Genomic DNA is digested with an enzyme such as *Rsa*1 (or *Hpa*II) that generates fragments of average length of an optimal size for PCR amplification (1000–2000 bp). Another advantage of using *Rsa*1 enzyme is that its recognition site occurs infrequently in DNA repeat sequences, thus minimizing the preferential cloning of repeat sequences. Next, DNA is ligated to a plasmid vector (e.g. pUC 18) and then enzymatically amplified, using in the vector universal primer binding sites that flank the insert DNA cloning site. These primers, the M13 forward and reverse primers, are as follows:

M13 forward sequencing primer:

5′-ACTGGCCGTCGTTTTAC-3′

M13 reverse sequencing primer:

3′-GTCCTTTGTCGATACTG-5′

The cloned DNA is amplified using PCR with M13 primers. Therefore, only one pair of oligonucleotide primers is used for the simultaneous amplification of many different DNA inserts. PCR amplification is performed according to the following thermal profile: 25 one-minute cycles of denaturation at 94 °C (first cycle, 5 min), 1 min of annealing at 55 °C, and 2 min of primer extension at 72 °C. Following the initial amplification, the DNA inserts are cleaved with a second enzyme (*Eco*RI) that flanks the *Rsa*1 site. The inserts are subsequently subcloned into a second plasmid vector and propagated in the appropriate bacterial host to generate the band-specific recombinant minilibrary. This procedure was first employed to clone specific genes from human chromosome 8 from Langer–Giedion syndrome patients. This cloning method offers several advantages. Cloning in plasmid vectors is easier than cloning in phages and can be more rapidly characterized. Also, the smaller size of the vector renders DNA inserts in plasmid vectors more amenable to enzymatic amplification and direct sequencing than they are in phage vectors. The introduction of PCR allows the amplification of a population of clones that would otherwise go undetected. Finally, the use of PCR significantly reduces the number of chromosomal fragments initially required for cloning.

A similar method in which the microdissected DNA was ligated to a linker adapter molecule instead of a plasmid vector followed by PCR amplification was described. The linker adapter consisted of a 24-nucleotide molecule with a terminus complementary to the *Mbo*1 enzyme recognition sequence. The *Mbo*1 linker adapters have the following sequence:

5′-GATCTGTACTGCACCAGCAAATCC-3′
3′-ACATGACGTGGTCGTTTAGG-5′

The linker adapter is formed by annealing a mixture containing 100 $\mu g\,mL^{-1}$ of each oligonucleotide at 58 °C for 1 h. Prior to the annealing step, the 24-mer oligonucleotide component carrying the 5′ *Mbo*1 complementary overhanging end is phosphorylated. This step is necessary to prevent the formation of tandem arrays of linkers during ligation, which may interfere with the amplification of chromosomal DNA. Following chromosomal DNA extraction and digestion as described earlier, the DNA is ligated to the *Mbo*1 linker adapter at 19 °C for 16 h. PCR amplification is carried out as follows: 35 one-minute cycles of denaturation at 94 °C, primer annealing (2 min, 52 °C), and primer extension (3 min, 73 °C). The amplified DNA is subsequently cloned into *Bam*HI linearized Bluescript plasmids after extraction and gel purification. The library is then propagated in competent bacteria.

4.1.3 PCR Amplification of Chromosomal DNA

The third method of microcloning employs PCR amplification of microdissected chromosomal DNA fragments without prior manipulation. The PCR reaction product is examined for self-completeness, is radioisotopically labeled, and is used to probe a more complete recombinant library. In this direct method, DNA sequences from a specific chromosomal region are isolated by amplification of the microdissected DNA with PCR, using a set of universal primers containing a series of degenerate base sequences. The amplification product would represent a heterogeneous population of DNA sequences. Direct PCR amplification of microdissected DNA has been recently employed to isolate genes from band 2F of

the *Drosophila* polytene X chromosome using degenerate ''universal'' primers. More recently, libraries of specific human chromosome bands were constructed using universal primers and PCR. The use of *Alu*-specific primers to screen for human genes in complex DNA mixtures has been described. Probes generated from microdissected chromosomal DNA fragments with *Alu*-PCR have been used to localize specific chromosomal sequences in YAC recombinant clones. They were also used to generate sequence-tagged sites (STSs) from discrete chromosomal regions. Direct PCR amplification of microdissected DNA has a few advantages over the methods that employ cloning first. Direct amplification of picogram amounts of DNA obviates the time-consuming steps that involve restriction enzyme digestion, ligation, and subcloning. This approach minimizes the loss of minute starting quantities of DNA during the various manipulations.

Most important, the clones constituting the final library contain chromosome-specific DNA inserts of considerably larger size, depending primarily on the recombinant library that was screened. This method does not involve cloning; hence the size of the library depends entirely on the efficiency and completeness of PCR amplification.

The completeness of the PCR product is dependent on the sequence of primers used and the PCR reaction conditions (e.g. annealing temperatures during the early cycles, primer extension times), concentration of deoxynucleoside triphosphates, the quality of DNA polymerase, and finally the number of cycles (usually 60–90) required to amplify sufficient amounts of DNA inserts containing unique sequences.

The term *universal primers* refers to a mixture of oligonucleotide sequences that lack absolute complementarity to the target template sequences. They contain multiple degenerate bases. When one is using these primers in PCR amplification and selecting lower PCR annealing temperatures (46–48 °C), complementary sequences that contain significant homologies can be amplified. For example, the following primer was recently used to generate a probe library from *Drosophila* polytene chromosome fragments:

5′-TTGCGGCCGCATTNNNNTTC-3′

With complete degeneracy at positions 4 to 7 from the 3′ end, authentic DNA sequences from the *Drosophila* genome were isolated. A similar primer has been described in PCR amplification of DNA from human chromosomes. This 22-mer, however, contains complete degeneracy at 6 nucleotides (positions 11–16), with the following sequence:

5′-CCGACTCGAGNNNNNNATGTGG-3′

In general, a nonspecific primer should have the following structure from 5′ to 3′ ends: two or more protective (cap) nucleotides (e.g. TT and CCGA in the primers just described), four to six nucleotides with complete degeneracy, and finally, a terminal 3′ sequence that occurs at high frequency in the genome of the species in which DNA is amplified, such as TTC and ATGTGG in the *Drosophila* and human genomes respectively. Furthermore, a restriction endonuclease site (e.g. *Not*I and *Xho*I, in the just-described primers respectively) may be added for easy recognition of the PCR product and subsequent cloning in an appropriate vector. The *Alu* repeats (SINEs) and L1 repeats (LINEs) are short interspersed repeated DNA elements distributed throughout the genomes of primates. *Alu* elements are dimeric in

structure and are composed of two tandomly arranged halves. *Alu* repeats are approximately 300 bp long and are present at a copy number in excess of 10^6 per haploid human genome equivalent. The L1 repeats, however, are present in 10^4 to 10^5 copies per genome. *Alu* and L1 repeats occur preferentially in light Giemsa bands and dark Giemsa bands respectively.

Oligonucleotide primers based on human *Alu* sequences and L1 sequences were designed and used in PCR amplification of human DNA sequences from hamster–human hybrid cells containing a single human chromosome. The following primers were utilized:

Alu-559: 5′-AAGTCGCGGCCGCTTGCA-
GTGAGCCGAGAT-3′

Alu-517: 5′-CGACCTCGAGATCT(C/T)-
(G/A)GCTCACTGCAA-3′

L1Hs: 5′-CATGGCACATGTATACATA-
TGTAAC(T/A)AACC-3′

A drawback of direct amplification using degenerate primers, however, is that minute quantities of any contaminant DNA will also be amplified along with the chromosomal DNA. Therefore, certain precautions are necessary. Chromosome spreads should be dropped on clean, sterile coverslips. All solutions and even the oil used in the microdissection system should be filter-sterilized and placed under UV light for several hours or overnight before use.

Also, glass cutting needles should be acid/alcohol washed and sterilized under UV light. Pipettes should be designated for use in chromosome fragment amplification only. Occasionally, the *Thermus aquaticus* DNA polymerase used in PCR reactions becomes contaminated with foreign DNA (bacterial or yeast) that served as the PCR template. Therefore, the lots of enzyme should be tested before use in microdissection experiments. No PCR product should be detectable after three consecutive rounds of amplification in the absence of template DNA. Finally, it is customary to run a ''water control'' (reaction without DNA template) in tandem with each PCR amplification to ensure that the test reaction DNA product was generated from chromosomal fragments.

Direct amplification of microdissected chromosomal DNA also has unique problems. Often, one or more amplified products cannot be visualized on agarose gel after one round of PCR cycle. This situation can be rectified, however, by increasing the number of chromosome fragments in the PCR reaction and increasing the primer concentration ($\geq$1 μg). More important, decreasing the annealing temperature of the initial thermal cycles of PCR (27–30 °C) was found to enhance the amplification product. Running an additional round or two of PCR amplification is recommended. This is accomplished by removing an aliquot (1/10th) from the first round and repeating the PCR. Chromosomal DNA that is precut with restriction enzyme (e.g. *Hpa*II) would generate a homogeneous population of fragments, amenable to uniform PCR amplification. A more troublesome problem – the isolation of large number of clones containing repeat sequences – is the result of the combination of an abundance of these sequences throughout the human genome and the low stringency of PCR annealing temperatures. The problem can be minimized (but not avoided) by fine-tuning the annealing temperature in the initial PCR cycles to a point that biases the PCR toward amplification of unique sequences. Alternatively, following the generation of PCR product it may be useful to perform

suppression hybridization of the product to *Cot*1 or genomic DNA to remove repeat sequences before the product is used in the screening of recombinant libraries.

4.2 Analysis of Cloned DNA

Once a chromosomal region–specific recombinant DNA library has been constructed, it should be tested for its completeness and complexity. One should also verify whether the cloned DNA originated from the microdissected fragment of interest. First, DNA insert size and range must be determined. Second, the percentage of clones containing repeat and unique sequences must be calculated. Third, the percentage of the total microdissected DNA fragments that has been cloned is determined. Fourth, cloned sequences are localized to the respective chromosomal regions by *in situ* hybridization or Southern hybridization to region-specific DNA.

For determination of the average DNA insert size and range, a number of clones (30–50) are picked at random, and the insert DNA is released from the cloning vector by digestion with the appropriate restriction enzyme and is fractionated on an agarose or polyacrylamide gel electrophoresis apparatus using appropriate DNA markers. The restriction enzyme digestion of each of the randomly picked clones provides a pattern that is indicative of the number of unique clones in the library. Estimation of the average size and range of cloned inserts as well as determination of the number of independent clones is used to calculate the completeness of the library.

Next, the random clones can be used to identify the portion of recombinant clones that contain repeat sequences. DNA inserts are transferred to a nitrocellulose filter and probed with total genomic human DNA that is radioisotopically labeled by nick translation. If the library were generated in a completely unbiased manner, a large number (~80%) of these clones would contain repeat sequences and would result in positive hybridization. Unique sequences are determined by digesting total genomic DNA with several restriction enzymes (e.g. *Bam*HI, *Eco*RI, *Pst*I) and performing a Southern hybridization. Recombinant DNA inserts from individual clones are radioisotopically labeled and used to hybridize to restriction polymorphic genomic fragments under conditions that favor unique sequences (65–68 °C).

An ideal library generated from a chromosome fragment would consist of a series of recombinant DNA clones containing overlapping sequences that span the entire chromosomal region. The size of a library of completely random fragments of genomic DNA needed to ensure representation of a particular sequence of interest is dictated by the size and number of the cloned inserts and the size of the chromosomal fragment originally dissected. The following formulas are used to calculate the percentage of DNA that would be cloned from a chromosome fragment. Theoretically, the number of clones that is required to achieve a library of a 99% probability of containing a particular sequence is

$$N = \frac{\ln(1 - P)}{\ln(1 - I/G)}$$

where P is the desired probability, I is the insert size, G is the genome size of the chromosome fragment, and N is the necessary number of clones. For example, to generate a recombinant library of average insert size 2.4 kb (a typical insert size following *Eco*RI digestion), the number of clones necessary to ensure

a 99% probability of cloning the entire 10 Mb fragment is determined as follows:

$$N = \frac{\ln(1 - 0.99)}{\ln[1 - (2.4 - 10^3/10^7)]} = 19\,000$$

The actual number of clones obtained would be determined by factors such as the efficiency of the cloning method, the cloning capacity of the vector, the relative number and size of clonable and nonclonable DNA sequences in the target DNA, and the degree of DNA degradation during the process of chromosome preparation and library construction. Therefore, the percentage of the total DNA that has been cloned would be determined as follows:

$$\%\ \text{fragment DNA cloned} = \frac{\begin{array}{c}\text{experimental number of clones}\\ \text{obtained} - \text{mean average}\\ \text{insert size}\end{array}}{\text{fragment DNA content}} \times 100$$

Evolutionarily conserved DNA sequences are indicative of potential structural gene sequences. To determine the *potential structural genes* in the library, the gene(s) of interest can be hybridized to genomic DNA from a number of species using relatively stringent hybridization conditions. The relatedness of a sequence among various species is readily identified by its hybridization to genomic DNA from these species. Genomic DNA from a number of species is now commercially available on biomembrane blots (e.g. Biomap Evo blots, BIOS), sometimes also referred to as *Zooblots*. These blots contain genomic DNA from human, cat, dog, sheep, pig, cow, rabbit, rat, and mouse. Potential structural genes are identified as those that hybridize to DNA sequences from at least three species. Once a structural gene has been recognized, its sequence can be used to isolate the full-length expressed gene from a cDNA library of the appropriate tissue. Alternatively, structural genes may be identified by directly hybridizing cloned genomic DNA to cDNA libraries under conditions that suppress hybridization of repeat sequences. Following the detailed analysis of the recombinant clones, it is also necessary to perform *in situ* hybridization to confirm whether the clones map to the microdissected chromosomal region of interest. In addition to identifying the chromosome on which a gene lies, fluorescence *in situ* hybridization (FISH) helps position the gene of interest at a resolution of about 1 to 2×10^7 bp (0.5%) of the genome. Genomic clones as well cDNA clones can be used in FISH. Unique sequences contained in large-insert DNA probes, such as cosmid and YAC clones, can be used directly in FISH following the suppression hybridization of repetitive sequences first with unlabeled genomic DNA or repeat sequences (e.g. *Cot*1 DNA).

The fluorescent labeling system is based on the modification of the DNA probe with biotin. The probe DNA is labeled using nick translation. Biotin is detected by its binding to avidin or streptavidin coupled to enzymes such as horseradish peroxidase or to fluorochromes. Fluorescent *in situ* hybridization of metaphase chromosome spreads involves two steps:

1. Denaturing the two strands of the chromosomal DNA contained in a metaphase spread on a coverslip, followed by hybridization to a denatured fluorescent-labeled oligonucleotide probe.
2. Localization of the hybridization signal to a specific chromosomal band region.

Significant amplification of the signal can be achieved using a second layer of a biotinylated antiavidin antibody and a third

layer of fluorochrome-coupled avidin. The DNA to be used for *in situ* work should be of the highest quality. The probe should be devoid of repetitive sequences. Any repeat sequences that are present must be removed by subcloning into a suitable vector or by using suppression hybridization in the detection reaction. All other components for *in situ* hybridization are readily available in kits from biochemical companies specializing in molecular biology products.

There are at least three methods for the identification of specific chromosomes and chromosomal bands. GTG banding followed by FISH and propidium iodide fluorescence staining is commonly used. In this case, FISH is performed according to standard procedures, whereupon photomicrographs from FISH and GTG banding are compared to identify the chromosome(s) harboring the gene of interest. A second method involves FISH hybridization followed by R-banding using Hoechst dye. Chromosomes are stained with Hoechst 33258 dye for 15 min after FISH, UV-irradiated for 20 min at 365 nm, and then counterstained with propidium iodide. FISH signals and R-banding using propidium iodide or DAPI can be visualized simultaneously. The third method takes advantage of the newly described chromosome painting probes. A target chromosome can be readily identified using a specific painting probe with a different fluorochrome that issues from the gene to be mapped. Mapping of a new gene to the chromosomal region from which it was dissected is a crucial step before any further molecular analysis is done. The success of an *in situ* experiment depends on several critical factors. The factors that contribute significantly to the fluorescent signal include the specific activity of the probe used, its length, and the effective concentration of probe per slide. Furthermore, conditions for chromosome preparation, banding, and staining must be optimized accordingly. Often, chromosomes do not band well enough to identify individual chromosomes. Overstaining with the counterstaining dye may quench or diminish the hybridization signal. Distortion of chromosomal bands following the FISH procedure can be minimized by performing GTG banding first. Finally, the problem of background noise can be considerably alleviated by selecting narrow excitation band optical filters.

5
Laser-capture Microdissection (LCM)

Molecular examination of pathologically altered cells and tissues at the DNA, RNA, and protein level has revolutionized research and diagnostics in pathology. However, the inherent heterogeneity of primary tissues with an admixture of various reactive cell populations can affect the outcome and interpretation of molecular studies. Microdissection of tissue sections and cytological preparations is being increasingly used for the isolation of homogeneous, morphologically identified cell populations, thus overcoming the obstacle of tissue complexity.

In conjunction with sensitive analytical techniques, such as the polymerase chain reaction, microdissection has aided in the precise *in vivo* examination of cell populations, such as carcinoma *in situ* or the malignant cells of Hodgkin's disease, which are otherwise inaccessible for conventional molecular studies. To further implement this concept, the National Cancer Institute developed laser-capture microdissection. LCM is a technique that permits the isolation of morphologically

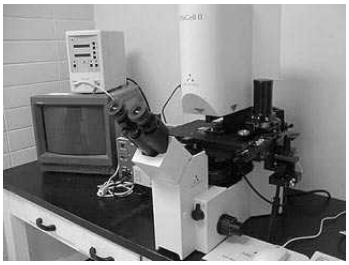
defined cell populations from specific microscopic regions in complex primary tissues using tunable laser beams. Once captured, the DNA, RNA or protein can be extracted from the isolated cells for molecular analyses. The minute samples may be analyzed by conventional PCR, reverse-transcription (RT)-PCR or polyacrylamide gel electrophoresis for specific macromolecular changes.

LCM is based on the selective adherence of visually targeted cells and tissue fragments to a thermoplastic polymer membrane coating [ethylene vinyl acetate (EVA)]. The membrane is attached to a rigid support and is placed in contact with the dehydrated tissue section. The system consists of an inverted microscope, a solid-state near-infrared laser diode, a laser control unit, and a joystick-controlled microscope stage with a vacuum chuck for slide immobilization, a CCD camera, and a color monitor. The LCM microscope may be connected to a personal computer for additional laser control and image acquisition. The thermoplastic membrane used for the transfer of selected cells has a diameter of approximately 6 mm and is mounted on an optically clear cap, which fits on a standard 0.5 mL microfuge tube for subsequent tissue processing. The cap is suspended on a mechanical transport arm and placed on the desired area of the dehydrated tissue section under standard pressure. After visual selection of the desired cells guided by the positioning beam, a selected cell cluster is precisely activated by a near-infrared laser pulse that results in focal melting of the EVA membrane. The absorption maximum of the membrane is near the wavelength of the laser. The melted polymer expands into the section and fills the hollow spaces present in the tissue. The polymer resolidifies within milliseconds and forms a composite with the tissue. The adherence of the tissue to the activated membrane exceeds the adhesion to the glass slides and allows selective removal of the desired cells. Laser impulses between 0.5 and 5 ms in duration can be repeated multiple times across the whole cap surface, which allows the rapid isolation of large numbers of cells. The selected tissue fragments are harvested by simple lifting of the membrane, which is then transferred to a microfuge tube containing the buffer solutions required for the isolation of the molecules of interest.

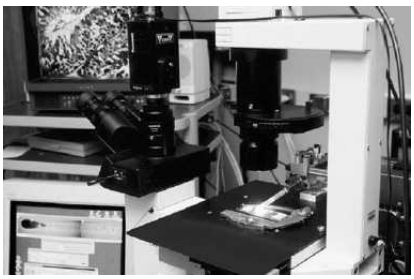
The minimum diameter of the laser beam of an LCM microscope is currently 7.5 μm, the maximum diameter 30 μm. Because most of the energy is absorbed by the membrane, the maximum temperatures reached by the tissue upon laser activation are in the range of 90 °C for several milliseconds, thus leaving biological macromolecules of interest intact.

After the first description of the initial NIH LCM, it was soon followed by the development of a commercially available LCM microscope. Currently, the second generation of this instrument (PixCell II; Arcturus Engineering, Mountain View, California, USA) illustrated in Fig. 6 is on the market. The technique has proven to be an effective routine microdissection technique for subsequent macromolecular analysis in many laboratories around the world. LCM has been applied to a wide range of cell and tissue preparations including paraffin wax–embedded material and fresh and frozen biopsies.

A prerequisite for this technique is the availability of histological dyes that do not interfere with downstream analysis of the sampled genetic material. Ehrig and colleagues have examined the effect of four histological nuclear dyes (methyl green, hematoxylin, toluidine blue O, azure B)



(a)



(b)

Fig. 6 (a) Arturus PixCell II Laser-capture Microdissection System that consists of an Olympus inverted microscope with 4×, 10×, 20×, and 40× objectives, near-infrared diode laser, user-selectable 7.5 mm, 15 mm, and 30 mm spot sizes, CCD color camera and monitor, image-archiving workstation. (b) Close-up at the laser beam to capture a single cell.

on TaqMan polymerase chain reaction amplification of genomic DNA prepared from fixed and frozen tissue for laser-capture microdissection. They concluded that DNA recovery from LCM-sampled tissue is independent of the histological stain chosen to highlight nuclear detail. The use of immunohistochemical stains allows the selection of cells according to phenotypic and functional characteristics. Depending on the starting material, DNA, good quality mRNA, and proteins can be extracted successfully from captured tissue fragments.

More recently, LCM has been refined to capture single cells in a specimen. The capture of individual cells with a new NIH LCM microscope epi-irradiates the EVA polymer overlying individual cells with 1-ms laser pulses focused to 6 µm. A computer-controlled arm precisely positions a 40-µm-wide strip of a cylindrical EVA surface onto a sample with a light contact force (ca. 0.1 g). The small contact force and contact area on the film on the sample diminishes nonspecific transfer to negligible levels.

With the advent of LCM, cDNA libraries are being developed from pure cells obtained directly from stained tissue, and microhybridization arrays of thousands of genes can now be used to examine gene expression in microdissected human tissue biopsies of various specific pathological lesions, especially malignant neoplasms. Similarly, the use of LCM is sufficient to isolate nanogram quantities of high-quality RNA. Together with the use of several internal standards and microcapillary electrophoresis of input RNA, two rounds of linear molecular amplification have been used to generate sufficient quantities of labeled target for hybridization to high-density oligonucleotide expression arrays. Results demonstrate that the technique is reproducible and generates only modest biasing of the original transcript population.

For further details regarding applications of LCM, the reader is encouraged to refer to the review article by Fend and Raffeld. It is an excellent source for determining the pros and cons of LCM versus conventional microdissection methods, and the limitation of technology. The review also discusses the current applications with references to DNA analysis, gene expression analysis, global

expression profiling, and single-cell applications. With regard to the technology itself, protocols, sample preparation, and signing up for training, visiting the following NIH website is recommended. (http://dir.nichd.nih.gov/lcm/LCM.HTM)

6 Applications of Chromosome and Tissue Microdissection

A recent three-year period literature review of the potential uses of DNA (RNA and protein) obtained by microdissection resulted in more than 600 reports on the application of chromosome and tissue microdissection to generate recombinant DNA clones from various human, mouse, rat, plant, and a number of other species. With the inclusion of LCM, there is a plethora of articles on the use of RNAs and proteins derived predominantly from human tissue archives and biopsies to delineate several diseases. The applications of microdissection can be grouped into eight categories.

1. Direct analysis of microdissected chromosomal DNA following PCR amplification.
2. Generation of recombinant DNA libraries from specific chromosomal regions.
3. Isolation of expressed genes localized to specific regions by probing cDNA libraries with amplified microdissected DNA from that region.
4. Study of chromosome abnormalities in cancer cells
5. Investigation of other specialized chromosomal structures
6. Gene transfer using chromosome fragments
7. Coupling microdissection with microarrays and proteomics technologies (DNA/protein microchips)
8. Incorporation of microdissection techniques in modern pathology

6.1 Direct Analysis of the PCR Product of Microdissected Chromosome Fragments

If the sequence of the gene of interest is known, gene-specific oligodeoxynucleotide primers can be synthesized and used in a PCR diagnostic for that gene. DNA from a microdissected fragment serves as a PCR template using gene-specific primers to localize (or exclude) a gene from that chromosome region. Also, if the spatial relationship of multiple genes in a specific chromosome region is known, target sequences can be amplified by PCR to detect structural alterations (deletions or rearrangements). In these experiments, a limited number of chromosome fragments from one region are dissected and target sequences are amplified using site-specific oligonucleotide primers. The inability to generate a PCR product using DNA from the affected region (in the presence of appropriate positive controls) is indicative of the absence or rearrangement of the gene in that region. Using this method, it was possible to map the breakpoints on chromosome 11 that are present in a number of translocations associated with human leukemia. When a translocation is identified by karyotype analysis but the chromosome of origin of the derivative chromosome is ambiguous, analysis of the microdissected translocation site may be helpful. One strategy involves the microdissection of the region of translocation, followed by *in vitro* amplification (PCR) using nonspecific primers. The PCR product is fluorescently labeled and hybridized to a normal karyotype to identify the chromosome that participated in the translocation. This method (called

micro-FISH) is rapid and may help identify complex karyotypes.

A new multicolor-banding technique has been developed that allows the differentiation of chromosome region–specific areas at the band level. The technique is based on the use of differently labeled overlapping microdissection libraries. The changing fluorescence intensity ratios along the chromosomes are used to assign different pseudocolors to specific chromosome regions. Weimer et al. have used that advantage and have further refined micro-FISH by combining the techniques of fluorescence *in situ* hybridization (FISH) and chromosomal microdissection in one experiment. Rearranged chromosomes were first identified by multicolor-FISH; the fluorophore-labeled derivative chromosomes were directly isolated by microdissection and reverse painted to identify the breakpoints. Thus, identification of the composition, origin, and breakpoints of rearranged chromosomes was rapidly accomplished.

6.2 Recombinant DNA Libraries Generated from Microdissected Chromosome Fragments

Recombinant DNA libraries can be generated from microdissected chromosomal fragments either by direct microcloning or by PCR-based methods as described earlier. Although methods in current use yield libraries that represent only a small fraction of unique sequences within the dissected region, these recombinant clones can be valuable as entry sites into poorly defined chromosomal regions. Also, they may be used as probes to identify and localize clones from genomic libraries that contain large DNA inserts. Chromosome microdissection has been used increasingly in genomic projects to "fill in" specific chromosome regions that are poorly mapped. Microdissection of a poorly defined chromosomal region, followed by cloning and sequencing unique sequence clones, could generate a pool of potential landmarks or tracts of DNA sequences 200 to 250 bp in length. Such entities, called *sequence-tagged sites* (STSs), are potentially useful in establishing a physical map (at the base sequence level) of human chromosomes. Chromosome microdissection may be useful in constructing "contig maps" (a series of clones representing overlapping regions of the genome). Microdissected DNA is cloned and amplified by PCR and used as a probe to screen genomic libraries that contain larger DNA inserts (e.g. cosmid, BAC or YAC libraries) under conditions that suppress repeat-sequence DNA.

6.3 Isolation of Transcribed Sequences Using Microdissected DNA as a Probe

Mapping expressed genes to specific chromosome regions can also be accomplished using radioisotopically labeled microdissected DNA as probes in hybridization experiments with appropriate cDNA libraries. This calls for sequential screening of cDNA libraries using plaque hybridization methods. More recently, methods such as the capture approach utilizing biotin-labeled probes bound to streptavidin with magnetic beads are useful. A large number of inheritable diseases and traits have been mapped to chromosome regions using genetic linkage methods. The isolation of causative genes can be rapidly accomplished by using chromosome microdissection to generate a library restricted to DNA sequences from the region associated with the disease. Once

clones that are within a million base pairs of the disease locus have been isolated, other molecular biological techniques may be used to isolate the gene of interest. As an example, chromosome microdissection was used to isolate a novel oncogene (eIF-5A2 initiation factor) from human ovarian cancer. In this disease amplification of 3q25–q26 constitutes one of the most frequent chromosomal alterations. By hybrid selection using 3q26 band-specific DNA, transcribed sequences (among which eIF-5A2) were isolated from a primary ovarian cancer containing high-copy number 3q26.

Table 1 lists a number of disease-related genes that were isolated by using microdissection and cloning methods.

Similar chromosome band–specific expression fragments were obtained from probe pools generated by microdissection of murine, bovine, swine, equine, and rice chromosomes. The pool DNA was used as probes to screen cDNA libraries of the respective species.

6.4 Study of Chromosome Abnormalities in Cancer Cells

Many nonrandom chromosome abnormalities are associated with specific cancer cell types. Microdissection may help advance our knowledge about the structure of such aberrant chromosomes and their behavior during mitosis, as well as delineate cytogenetic aberrations that cannot be identified by conventional chromosome analysis. Translocation sites may be microdissected directly and cloned to expedite the isolation of the causative chimeric (fusion) gene. Also, regions corresponding to a deletion site may be dissected from the normal chromosome. Clones may be used as probes in *in situ* hybridization experiments to delineate whether the

Tab. 1 Recombinant DNA libraries from microdissected chromosome regions associated with inheritable disorders in human.

Disease	*Chromosome region*
Adenomatous polyposis coli	5q21
Beckwith–Wiedmann syndrome	11p15.5–pter
Cystic fibrosis	7q
Down's syndrome	21q
Fragile X syndrome	Xq27–Xq28
Langer–Giedion syndrome	8q24.1
Meningioma	22q12–q13
Neurofibromatosis type II	22
Prader–Willi syndrome	15q11.1–12
Trichorhinophalangeal syndrome type I	8q23–qter
Wilms' tumor/anoridia	11p13
Waardenburg syndrome type I	2q33–qter
Multiple endocrine neoplasia type 2A	10p11.2–q21.1
Small-cell lung cancer and renal cell carcinoma	3p14–p21
Angelman syndrome	16p11.2
Ovarian cancer	3q25–q26
Acute nonlymphocytic leukemia	4p
Germ cell Tumors	12p

isolated sequences fall within the region encompassed by the deletion. For example, using a chromosome 9p–specific microdissection probe showed chromosome 9p anomaly resulting from two translocations [t(9; 18)(p12; p11.2) and t(1; 9)(p12; p12)] in polycythemia vera patients. Similarly, chromosome microdissection and reverse painting of aberrant chromosome 2 revealed a 2q33–q35 deletion in lung hypoplasia.

6.5 Investigation of Other Specialized Chromosomal Structures

Recombinant libraries from microdissected chromosomes can be very useful in genetic analysis of specialized chromosome structures, in genomic sequencing projects, and for the characterization of disease-related genetic loci. Specialized chromosome regions are particularly amenable to microdissection and cloning. These regions include common structures such centromeres and telomeres and the regions adjacent to these structures, short arms of acrocentric chromosomes, translocations, and fragile sites. Also, the structural basis of light and dark Giemsa banding as well as of the banding patterns observed with newer staining methods can be investigated.

In addition to chromosome band–specific libraries (probes), microdissection in combination with reverse-painting fluorescence *in situ* hybridization (FISH) has proven to be a very effective method to identify the origin of less common but important structures such as homogeneous staining regions (HSR), marker chromosomes, ring chromosomes, small accessory chromosomes (SACs), and directed isolation and mapping of microsatellite sequences.

Regions of gene amplification (homogeneous staining regions) are relatively large structures that can be microdissected easily for cloning and molecular analysis. For example, the chromosomal origin of HSR in neuroblastoma was identified as coamplification of chromosome bands 2p13 and 2p24 by chromosome microdissection and FISH. A microdissection-specific probe isolated from HSR in cells of transitional-cell carcinoma of the bladder revealed a new region (1p31–p32) that is amplified in primary tumors in addition to the previously known regions involving amplifications in chromosomes 6p22, 7p11, 9p23–pter.

In myelodysplastic syndromes (MDS), karyotypic aberrations identify subgroups of patients with distinct clinical–morphological features and can be relevant in risk assessment of developing leukemia. Often, conventional cytogenetic analysis is not sufficiently informative due to the presence of numerous unrecognizable markers. Microdissection of these markers followed by reverse-paint normal karyotypes may resolve questions regarding their origin in cases of MDS in patients previously treated for cancer. Ring chromosomes are another example of a rare constitutional abnormality with inconsistent phenotypic features. The ring chromosomes were characterized using microdissection in combination with degenerate nucleotide-primed polymerase chain reaction (PCR) and reverse painting (micro-FISH). This method made it possible to determine the chromosomal origin of the ring chromosomes in detail in several diseases and thus to compare the phenotypes of similar cases. Reverse painting of microdissected chromosome 6 probe onto normal metaphase spreads revealed a small deletion of the terminal region of 6q26qter in cases of acute

myelogenous leukemia. Microdissection of a ring chromosome in another AML-M5 case disclosed a (8 : 15) translocation with overrepresentation of 8q22. The origin of a ring chromosome in a myxoid malignant fibrous histiocytoma (MFH) was also determined by microdissection and FISH analyses. Hybridization of the microdissected labeled DNA to normal metaphase cells revealed that the signal localized only to 20q. Three signals were seen in the tumor cells using either the microdissected 20q probe or the chromosome 20 centromeric probe, indicating the involvement of both the long arm and the centromere in the ring chromosome. Small accessory chromosomes (SACs) are often associated with the centromeres of other chromosomes. The occurrence of more than two SACs in a single individual is extremely rare. Recently, a case of multiple SACs was reported in two different tissues of a moderately mentally retarded male. Microdissection combined with regular FISH demonstrated that SACs were derived from the centromeres of different chromosomes.

6.6 Gene Transfer Using Chromosome Fragments

Gene transfer into tissue culture cells or embryos has become an exceptionally useful method for the functional analysis of the regulatory and coding regions of genes. These methods are also used to induce phenotypic changes in cells as well as in whole organisms. The preferred vehicle for gene transfer and expression is a cloned gene (usually a cDNA with the appropriate flanking regulatory regions, promoters, and enhancers). Alternatively, whole genomic DNA has been transferred, usually with dominant selective markers. Gene-transfer experiments using microdissected fragments from a specific chromosome region would have several potential advantages. Transfer of large contiguous DNA stretches from microdissected chromosome fragments allows the gene to be presented "in context" – that is, with its own promoters, enhancers, control regions, and introns. These DNA sequences may be critical to the appropriate cell-type-specific expression of the transgene. The gene or locus of interest does not have to be identified, isolated, and cloned prior to gene transfer. This ability would be particularly advantageous in cases of a disease-related locus that was mapped genetically to a chromosome band by linkage analysis but was not further characterized. The transfer of genes into embryos through the mediation of chromosome fragments may be a useful tool in generating animal disease models and in confirming genetic linkage studies that map disease-causing genes to specific regions. To be transferred to an animal, however, the disease must behave as a positive dominant-acting genetic trait; it may not be associated with a structural deletion. An obvious disadvantage of chromosome fragment–mediated gene transfer is that only single-copy gene transfer is technically feasible. There are several reasons for this limitation. One would be the size and amount of DNA accepted by the recipient cell and the labor-intensiveness of the methodology. Two, physical manipulation of large stretches of microdissected DNA and microinjection would undoubtedly result in shearing of DNA into smaller fragments. Although this method will result in position-independent integration, the transferred DNA will be subject to DNA methylation, controlled by genotype-specific modifiers, as occurs with other transgenes. Richa and Lo reported the first

gene-transfer experiment in 1989. Human centromeric DNA was successfully transferred to fertilized mouse ova and was detected in blastocysts, 15-day embryos, and a mouse was derived from an injected ovum. Microinjection of insoluble or partially solubilized chromatin particles is likely to be an inefficient vehicle for gene transfer. A microscope stage such as that designed by Hagag and Viola would overcome this problem. The circular rotating stage accommodates a depression slide to collect chromosome fragments and a culture dish to contain fertilized ova (Fig. 2b). The stage permits the collection of a large number of fragments. The DNA is solubilized using trypsin or proteinase K in a small aqueous drop that is placed under oil. Soluble DNA is then used in microinjection of ova during the same setting.

6.7 Coupling Microdissection with Microarrays and Proteomics Technologies (DNA/Protein Microchips)

The microarray expression analysis system has become one of the most widely used functional genomic tools. The system has features that make it widely used for profiling mRNA expression. Microarrays are constructed by mechanically arraying PCR-amplified cDNA clones or genes representing the collection of genes to be assayed at a high density on derivatized glass microscope slides. A relatively simple *x-y-z* stage robotic system is used to spot an entire set of genes from a microbial genome or tens of thousands of eukaryotic cDNA clones. The microarrays are queried in cohybridization assays using two or more fluorescently labeled probes prepared from the cellular phenotype of interest.

Hybridization is assayed using a confocal laser scanner to measure fluorescence intensities, which allows simultaneous determination of the relative expression levels of all the genes represented in the array. Expressed sequence tags (EST) are single-pass, partial sequences of cDNA clones used for gene discovery, identification, and mapping in humans and other organisms. Generally, cDNA clones are selected to represent as many unique transcripts as possible. The two most widely used ESTs are UniGene at the National Center for Biotechnology Information (NCBI) (http://www.ncbi.nlm.nih.gov/UniGene) and the Institute for Genomic Research (TIGR) Human Gene Index (http://www.tigr.org/tbd/hgi/hgi.html). Readers new to this technology may consult the excellent concise guide by Hegde et al. The article offers a discussion of protocols, instrumentation, and data analysis. Several microarray systems are commercially available in the market. The ScanArray 3000 (GSI Lumonics, Watertown, MA, USA) and Biorad VersArray (www.bio-rad.com/versarray) are examples. The affymetrix (Santa Clara, California) DNA chip is widely used.

A recent study has put to use the combination of microarrays and microdissection to elucidate the distinct molecular changes that occur at each progressive stage of prostate cancer. The cDNA generated from prostate cancer (tumor) and benign tissue (reference) samples were labeled with distinguishable fluorescent dyes and hybridized to a cDNA microarray consisting of known sequence motifs, each representing a gene of interest. The cDNA microarray was analyzed using a scanner, and fluorescence ratios were determined for each gene. Ratios were then imported into a database and analyzed using statistical algorithms. The data surveying method

assigns color intensity to ratios of gene expression: for example, shades of red represent genes that are upregulated in prostate cancer (1–4 fold increase); shades of green are downregulated (1–4 fold decrease); black, genes that are unchanged between tumor and benign tissue; gray, missing elements (not present). Selected genes were then validated at the transcript level using Northern blot or RT-PCR or at the protein level with immunoblots.

Similarly, the feasibility of combining LCM and cDNA microarray hybridization has been demonstrated in several reports showing reproducible differences in gene expression between normal and pathologic tissue samples. Furthermore, a combination of LCM, cDNA arrays, and real-time quantitative PCR was used to show altered gene expression patterns at various stages of breast cancer progression. Several expression libraries from purified cell populations derived from microdissected normal, preneoplastic, and neoplastic breast, prostate, ovary, lung, and liver tissues with large numbers of partially sequenced clones are already available at the CGAP website. (http://www.ncbi.nlm.nih.gov/ncicgap)

Knowledge of the gene sequence or the quantity of gene expression using DNA chips is not sufficient to predict the biological nature and function of a protein. The identification and quantitation of expressed proteins is more challenging. Proteomics is the global analysis of expressed proteins (including posttranslational modifications) and seeks to establish the relationship between genome sequence, expressed proteins, protein–protein interactions, and cell and tissue phenotype. The benefit of global protein analysis is immense because identification of distinctive protein signatures associated with cell function may provide novel therapeutic targets, molecular markers of disease, and increased understanding of determinants of cell phenotype.

Proteomics-based profiling uniquely allows delineation of global changes in protein expression patterns resulting from transcriptional and posttranscriptional control, posttranslational modifications, and shifts in proteins between different cellular compartments. Some of the current technologies for proteome profiling and the application of proteomics to the analysis of tumor tissues are being used concurrently with microdissection. Given that comprehensive expression profiles obtained using genomics and proteomics are highly complementary, a combined approach to profiling may well uncover expression patterns that could not be predicted using a single approach. Hanash used LCM and high-throughput microarrays/proteomics to study in parallel with Alzheimer's disease and showed that consistent with cDNA microarray evidence, the expression of proteins involved in synaptic activities was also altered in the brains of early Alzheimer's disease cases. The study demonstrated that protein chip arrays can be used to examine sequential changes in distinctive gene expression patterns in the brain as a function of the progression of Alzheimer's disease.

Currently, the most widely used proteomic tool for analysis of disease is two-dimensional protein gel electrophoresis (2-DE), which can display protein expression patterns to a high degree of resolution. 2D-PAGE is being complemented by new, exciting approaches to multiparametric protein characterization. As an alternative, an equally powerful technology is being employed to generate protein expression patterns from whole tissue extracts. The technology uses surface-enhanced

laser desorption/ionization (SELDI) that allows the retention of proteins on a solid-phase chromatographic surface (ProteinChip Array) with direct detection of retained proteins by time of flight-mass spectrometry (TOF-MS). The use of rapid, high-throughput mass spectrometric–based fingerprints of peptides and proteins may prove valuable for new molecular classification of human tumors and disease stages. Coupled with laser-capture microdissection, high-density protein arrays, antibody arrays, and small molecular arrays could have a substantial impact on proteomic profiling of human malignancies.

Differentially expressed proteins in normal and neoplastic tissues were recently analyzed by von Eggeling et al. by comparing the protein expression patterns generated using SELDI-based TOF-MS in cases of renal cell carcinoma, peripheral and central tumor tissue, as well as four microdissected cases of cervical intraepithelial neoplasia and three microdissected cases of cervix uteri carcinoma. By applying ProteinChip array technology, it was possible to investigate simultaneous and complex changes associated with tumor development and progression at the protein level in several cancers. In their landmark article, Petricoin et al. declared that the ultimate goal of proteomics is to translate the bench-side promise into bedside reality. It is to characterize the information flow through protein networks. This information can be a cause, or a consequence, of disease processes. Using cancer as a model disease, clinical proteomics applications are being developed to detect cancer earlier, to discover the next generation of targets and imaging biomarkers, and finally to tailor the therapy to the patient.

6.8 Incorporation of Microdissection Techniques in Modern Pathology

The last decade has witnessed a ''molecular'' revolution in pathology. Demonstrating that transcription of specific single genes or small gene sets and their protein products by *in situ* hybridization and immunocytochemistry has become routine in diagnostic and experimental pathology laboratories. A perhaps greater revolution is imminent with the application of more recently established and emergent technologies. These include new approaches to polymerase chain reaction (PCR); simultaneous studies of multiple genes and their expression using oligonucleotide and cDNA arrays; serial analysis of gene expression (SAGE); expressed sequence tag (EST) sequencing, subtractive cloning, and differential display; high-throughput sequencing; comparative genomic hybridization, multiplex fluorescence *in situ* hybridization (FISH) (spectral karyotyping); reverse chromosome painting; and knockout and transgenic organisms. Laser microdissection and micromachining, and new methods in bioinformatics, ''data mining,'' and data visualization are added to the list. The use of any combination of these molecular methods will profoundly change diagnosis, prognosis, and treatment targeting oncology and will elucidate fundamental mechanisms of neoplastic transformation. Individual susceptibility to specific diseases will become assessable and screening will be refined.

Microdissection of chromosomal translocations, breakpoints, HSR, marker and ring chromosomes, micronuclei, and reverse-painting normal metaphase chromosomes have shed light on the origin of these aberrations. Table 2 presents a

Tab. 2 Disease-specific chromosomal regions mapped by microdissection methods.

Disease	*Chromosomal region*
Adenocarcinoma of the lung	9q, 16p
Acute myelogenous leukemia (ETO gene)	8q22
Autism/mental retardation	4q21
Basal cell carcinoma	9q22.3
Cervical carcinoma	6p21.3
Colorectal carcinoma	5q, 18q
Congenital heart defect	6p22.1–6pter
Ductal carcinoma breast	11q22–q23
Esophageal adenocarcinoma	4q32–33
Glioma	10q23.3
Melanoma	10q24–25
Ovarian cancer primary	3q25–q26
Ovarian cancer metastatic	3p25–p26
Pancreatic carcinoid	8p12–22
Prostate carcinoma	16q
Psychomotor/growth retardation	13q22–q32, 5q31.3q33.3
Small-cell lung carcinoma	3q13.2
Urinary bladder carcinoma (EGFR gene)	7p11–p12

sample of the numerous lesions/diseases for which chromosomal aberrations have been mapped by various microdissection techniques. In some instances, a specific gene has been identified as being potentially involved in the etiology of the disease. In other instances inactivation or absence of tumor suppressor genes are being sought as the cause of the disease.

How is functional genomics likely to impact on the pathology laboratory? Important aspects of functional genomics in the post genome era include the LCM, DNA and cDNA microarrays, proteomic methods, collaborative human tissue banking, tissue microarrays, and pathobioinformatics. The role of mass spectroscopy in the analysis of RNA, DNA, and protein has expanded. The recent combination of LCM and high-throughput cDNA microarrays provides a unique opportunity to generate gene expression profiles of cells from various stages of tumor progression as it occurs in the actual neoplastic tissue milieu. This combination was put to use to monitor *in vivo* gene expression levels in purified normal, invasive, and metastatic breast cell populations from a single patient. Expression profiles were verified by real-time quantitative PCR and immunohistochemistry and were proven to be generally applicable to the study of progression of malignancy. Rubin has used LCM, cDNA microarrays, and tissue microarrays to validate the presence of differentially expressed genes in various stages of prostate cancer. Pasinetti et al. conducted a large-scale gene expression profiling study using LCM and a number of tumors and their normal counterparts (e.g. tumor and normal oral epithelium). About 600 genes were found to be associated with oral cancer. These included oncogenes, tumor suppressor genes, transcription factors,

xenobiotic enzymes, metastatic proteins, differentiation markers, and genes that have not been implicated in oral cancer. A conglomerate of such genes may create a database that provides a verifiable global profile of gene expression during carcinogenesis.

7 Summary

Chromosome and tissue microdissection and microcloning technologies have proven to be powerful tools that made possible the isolation of new genes from chromosomal regions in several human genetic disorders. Three different techniques to perform chromosome microdissection and a number of alternatives to isolate and characterize microdissected DNA are presented. Also, the more recent technology of laser-capture microdissection is discussed. LCM has added to our ability to isolate DNA, RNA, and protein from a minute number of homogeneous cell populations. Advances in PCR and FISH methods have substantiated the use of microdissection in many applications. Indeed, the combination of these technologies has facilitated the isolation of several novel genes from infinitesimal amounts of DNA or tissue, a task that would not be possible using conventional methods. More recently, microdissection is being coupled with microspot technologies (DNA and protein microchips). These combinations will undoubtedly expedite the identification of disease-specific genes and markers via global expression profiling.

Keywords

Chiral
Possessing a nonsuperposable mirror image (like left and right hands).

Chromophore
Chemical moiety that absorbs light through excitation of one of its electrons.

Circular Dichroism
The differential absorption of left- and right-circularly polarized light.

Circularly Polarized Light
The resultant from combining two beams of linearly polarized light (*vide infra*) of equal intensity, but orthogonal polarizations, with a phase difference of a quarter of a wavelength.

Linearly Polarized Light
A beam of light in which the electric fields of all the photons oscillate in the same plane (also called *plane-polarized light*).

Optical Rotation
The rotation of plane-polarized light by a chiral compound (equivalent to circular birefringence).

Proteins are chiral objects. Elements of local, regular structure, called *secondary structure*, within proteins have a distinct handedness. For example, α-helices are mostly right-handed. Proteins absorb ultraviolet light, exciting electrons into high-energy states. Plane-polarized light (such as that created by Polaroid sunglasses) is light that propagates in only a single plane. It is possible to generate circularly polarized light. Left- and right-handed circularly polarized light may be considered as two components of plane-polarized light. When plane-polarized light passes through a chiral medium, its plane of polarization is rotated. If the light excites an electronic transition, a chiral molecule will absorb the left- and right-handed circularly polarized components differently. This differential absorption is termed *circular dichroism*. Circular dichroism spectroscopy may be used to estimate quantitatively the secondary structure content of proteins, giving the fraction of residues in α-helices, β-sheets, turns, and in coil conformations. It is widely used to characterize proteins under equilibrium conditions and to measure the kinetics of protein folding and unfolding.

1 Chirality and Polarized Light

At a molecular level, much of matter is asymmetrical, like our left and right hands, which are mirror images. In the world of organic chemistry, many compounds have chiral centers, typically carbon atoms bonded to four different atoms or groups. Chiral compounds have two forms (left- and right-handed), which cannot be superimposed on each other by rotation, although they have the same chemical composition. The asymmetric character of chiral compounds induces different interactions with electromagnetic radiation, which gives rise to optical activity.

A beam of natural light is a set of electromagnetic waves propagating in a single direction, but with all possible orientations perpendicular to the direction of propagation. When it passes through a linear polarizer, only a single orientation is selected and we get linearly polarized light. It may be divided into two chiral components of equal intensity, left- and right-circularly polarized light (Fig. 1). The electric vector of each circularly polarized component rotates along the direction of propagation. The overall effect of these two vectors is a planar sinusoidal wave.

Circular dichroism (CD) spectroscopy is the differential absorption of left- and right-circularly polarized light by a chiral medium. When linearly polarized light passes through achiral molecules, the absorption of left- and right-circularly polarized light is equal and no CD spectrum results. However, when the medium comprises chiral molecules, such as peptides, proteins, or DNA, there is differential absorption. The resultant of these two components is an ellipse with a specific optical rotational angle (Fig. 1). CD spectroscopy is based on the observation of optical rotation or circular birefringence, which can reflect detailed information about the three-dimensional conformation of biomolecules. The differential absorption arises because the left- and right-handed circularly polarized components experience different refractive indices on passing through chiral molecules.

The absorbance of light by a sample is given by the Beer–Lambert law:

$$A = \log\left(\frac{I_0}{I}\right) = \varepsilon c l \tag{1}$$

where A is the absorption, c is the concentration in mol dm^{-3}, I_0 is the intensity of the incident light, l is the pathlength in cm, and ε is the molar absorption coefficient in units of $dm^3\ mol^{-1}\ cm^{-1}$. The differential absorption is then

$$\Delta A = A_L - A_R = (\varepsilon_L - \varepsilon_R) c l = \Delta\varepsilon c l \tag{2}$$

where $\Delta\varepsilon$ is the difference in the molar absorption coefficients for left- and right-circularly polarized components. This may also be described, removing the linear dependence on pathlength and solute concentration, by

$$\Delta\varepsilon = \varepsilon_L - \varepsilon_R = \frac{\theta}{cl} \tag{3}$$

where θ is the ellipticity in degrees. The ellipticity is equal to the ratio of the minor radius to the major radius of the now elliptically polarized light, that is A/B, as shown in Fig. 1, and it is related to the differential absorption by

$$\theta = 32.98\ \Delta A \tag{4}$$

For a peptide or protein, the mean residue ellipticity in units of degree $cm^2\ dmol^{-1}$ is defined as

$$[\theta] = 100\,\frac{\theta}{cl} = 3298\,\Delta\varepsilon = \theta \times 0.1 \times \frac{MRW}{cl} \tag{5}$$

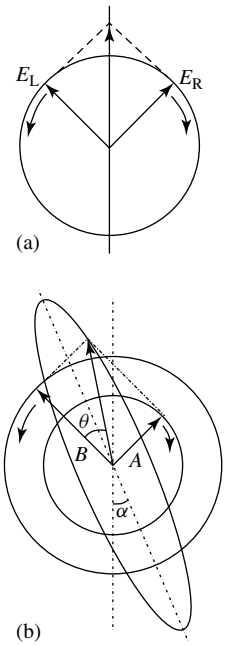

Fig. 1 (a) shows linearly polarized light with equally intense left- and right-polarized components (E_L and E_R). (b) Shows circularly polarized light with unequal left- and right-circularly polarized components. θ is the ellipticity and is the ratio of the minor axis to the major axis of the ellipse (A/B); α is called the *optical rotation*.

where c is the concentration in mg ml^{-1}; MRW is the mean residue weight, which is equal to molecular mass/$(N-1)$; N is the number of amino acid units and is typically one more than the number of peptide bonds, giving rise to the factor of $N-1$. The mean residue ellipticity is independent of the pathlength and concentration.

Although optical rotation is a dispersive measurement requiring the measurement over the complete spectrum, experimentally the measurements are confined to a relatively narrow wavelength range. In principle, CD can be measured with any frequency of electromagnetic radiation. However, in practice, most CD spectra are recorded in the ultraviolet–visible (UV–vis) region arising from electronic transitions. Since the early 1980s, new developments in optical and electronic technology have enabled optical activity measurements to be extended into the vibrational spectrum using both infrared and Raman techniques. We will focus on electronic CD, which is more commonly used, and will give only a brief description of vibrational optical activity.

2 Electronic Circular Dichroism

CD spectra arise from transitions that are electrically and magnetically allowed. When an electron of a molecule is excited from the ground state to a higher energy state, there is a change in the electric field of the radiation or the magnetic field or both. The change of the electric field causes a linear rearrangement of the electrons. The net linear displacement of charge during the transition is called the *electric transition dipole moment*, μ. The magnetic field change induces a circular rearrangement of electron density. The net circulation of charge is termed the *magnetic transition dipole moment, m*. In electronic absorption spectroscopy, bands arise from transitions that are either electrically allowed and magnetically forbidden or magnetically allowed and electrically forbidden. The oscillator strength, f, is proportional to the square of the electric transition dipole moment, μ^2, and corresponds to the area under a band in an electronic absorption spectrum. The rotational strength of a band in a CD spectrum is analogous

to the oscillator strength in electronic absorption spectroscopy. It is related to the product of the electric and magnetic transition moments and corresponds to the area under the band in the CD spectrum.

Electronic CD spectra may be divided into the far UV region (180–250 nm), the near UV region (250–300 nm), and the UV–vis region (300–700 nm). Absorption in the far UV region is dominated by the excitation of electrons on amide chromophores. It furnishes information on secondary structure (Fig. 2). In the near UV region, the CD arises from side-chain chromophores, such as aromatic groups and disulfide bonds. In this region, CD spectra can provide information on protein tertiary structure. The UV–vis region reflects the conformation and environment of the protein. Transitions in this region arise from chromophoric prosthetic groups, such as the heme group.

2.1 Far Ultraviolet

Peptide bonds are the key chromophores in proteins. To appreciate the origin of the CD of proteins, one needs to understand the electronic structure of the peptide bond. The valence shell of the peptide bond comprises four π electrons in three π orbitals (π_+, π_0, and the unoccupied π^*) and two electron pairs in two lone-pair orbitals (n and n′). The $n\pi^*$ and $\pi_0\pi^*$ electronic transitions of the peptide chromophore occur in the far UV region. The lowest energy transition is the $n\pi^*$ transition, which is polarized along the carbonyl bond. It is an excitation of an electron from a lone pair on the oxygen atom to an antibonding π orbital and occurs at 210 to 230 nm. It is magnetically allowed and electrically forbidden (Fig. 3). The transition energy is sensitive to the extent of hydrogen-bonding to the oxygen atom. In the lower symmetry of

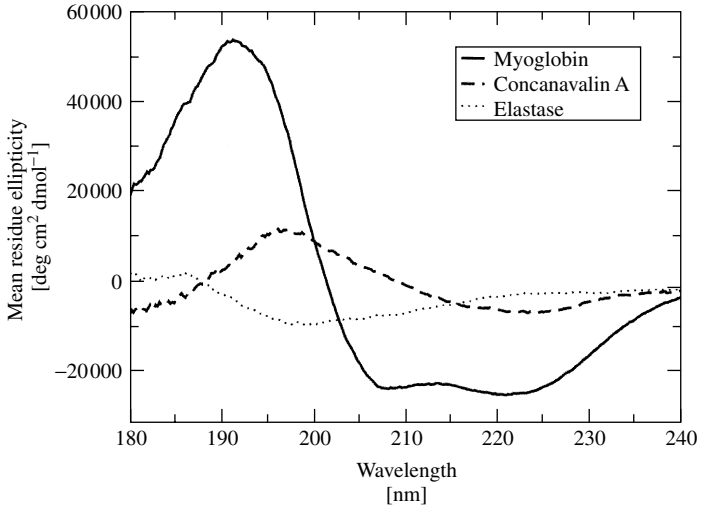

Fig. 2 The standard CD spectra for α-helix, β-sheet, and random coil, as typified by the proteins myoglobin, concanavalin A, and elastase respectively; the spectra are plotted from the freely available experimental data.

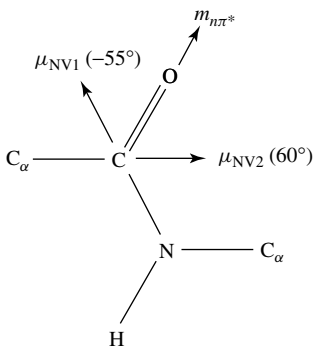

Fig. 3 The $n\pi^*$ and $\pi\pi^*$ transitions of the peptide chromophore in the far UV region. μ is the electrical transition dipole moment. m is the magnetic transition dipole moment.

a protein, the $n\pi^*$ transition is not strictly forbidden, but it is very weak. In solvents that lack hydrogen-bond donors, the $n\pi^*$ transition appears near 230 nm, while in aqueous solution, it is around 210 nm. The $n'\pi^*$ transition occurs at ~140 nm and is polarized perpendicular to the carbonyl bond.

The $\pi\pi^*$ transitions at 190 and 140 nm are electrically allowed. The first $\pi\pi^*$ transition, the NV_1 band, involves excitation of an electron from the nonbonding π orbital, π_0, to the π^* orbital. In secondary amides, the NV_1 band is observed around 185 to 190 nm, whereas in tertiary amides, it is closer to 200 nm. The second $\pi\pi^*$ transition, the NV_2 band, at 140 nm involves electronic excitation from the bonding π orbital, π_+, to the π^* orbital. The transition dipole moments of the two $\pi\pi^*$ transitions in secondary amides are approximately parallel (NV_1) and perpendicular (NV_2) to the C–N bond. The electric transition dipole moment of the $\pi_0\pi^*$ transition (NV_1) is about 3.1 D and that of the $\pi_+\pi^*$ transition (NV_2) is about 1.8 D. In an α-helix, the electric dipole coupling of the $\pi_0\pi^*$ (NV_1) transitions on neighboring residues results in two bands in the CD spectrum, one at ~190 nm and the other, a long-wavelength component, at ~208 nm. Interactions among the amide $n\pi^*$ and $\pi\pi^*$ transitions in a peptide are relatively delocalized and are significantly affected by environmental or local perturbations.

The arrangement of peptide bonds in a protein largely determines its CD spectrum in the far UV. The main-chain dihedral angles define the relative orientation of the backbone chromophores. If the dihedral angles for each amino acid residue were the same, the protein would form a perfectly regular helix (a β-strand may be viewed as a very narrow helix). Alternatively, an arbitrary set of (sterically allowed) dihedral angles would generate a random coil conformation. In reality, most secondary structures lie between these two extremes. The origins of the electronic CD of proteins can be understood by dividing the biopolymer into subunits, which do not have significant electronic exchange among them. This basic concept underlies theoretical calculations of protein CD spectra. Protein CD spectra arise from three types of interactions between $\pi\pi^*$ and $n\pi^*$ transitions of amides. Exciton interactions occur between degenerate or nearly degenerate $\pi\pi^*$ transitions on different peptide groups. An $n\pi^*$ transition and a $\pi\pi^*$ transition on different peptide groups may mix; this is also referred to as *μ–m coupling*. Finally, the $n\pi^*$ and $\pi\pi^*$

transitions on a single peptide group may mix – an interaction known as the *one-electron effect*. In an infinite helix, exciton interactions of $\pi\pi^*$ transitions on different peptide groups lead to three allowed transitions, one polarized parallel to the helix axis and two degenerate (equal energy) bands polarized perpendicular to the helix axis.

2.2 Near Ultraviolet

The near UV region, 250 to 300 nm, is also called the *aromatic region*. Because the peptide absorption in this area is at least an order of magnitude weaker than in the far UV region, a small number of aromatic chromophores have a distinct advantage. Bands in this region are due to $\pi\pi^*$ transitions from the aromatic side chains of histidine, phenylalanine, tyrosine, and tryptophan and $n\sigma^*$ transitions from disulfide groups. The indole of tryptophan has two or more transitions in the range of 240 to 290 nm with a combined maximum extinction coefficient $\varepsilon_{max}(279\,nm) \sim 5600\,dm^3\,cm^{-1}\,mol^{-1}$; tyrosine has one transition with $\varepsilon_{max}(274\,nm) \sim 1400\,dm^3\,cm^{-1}\,mol^{-1}$ and phenylalanine has one transition with $\varepsilon_{max}(258\,nm) \sim 190\,dm^3\,cm^{-1}\,mol^{-1}$. The cystine disulfide bond absorbs from 250 to 270 nm with $\varepsilon_{max} \sim 300\,dm^3\,cm^{-1}\,mol^{-1}$. The near UV CD also reflects the environment of aromatic groups. For example, the most red-shifted tyrosine feature should be due to tyrosine(s) in a highly polarizable environment, while the most blue-shifted are due to exposure to solvent. Although tryptophan has the most intense transition in this region, usually proteins have few tryptophans compared to the other aromatic groups, so the region tends not to be dominated by tryptophan transitions.

The disulfide group of cystine in many extracellular proteins has two well-characterized $n\sigma^*$ electronic transitions in the near UV region. The wavelengths depend on the dihedral angle of the disulfide band. This dihedral angle is normally approximately 90° in proteins, and the two $n\sigma^*$ transitions are degenerate, giving a single broad absorption band near 260 nm. As the dihedral angle deviates from 90°, the degeneracy is broken and one transition shifts to higher energy, with the other moving to lower energy. Disulfide contributions to a near UV CD spectrum are distinguishable from those of aromatic side chains, because the former are much broader.

3 Vibrational Circular Dichroism

Vibrational optical activity consists of two complementary spectroscopic areas, vibrational circular dichroism, and vibrational Raman optical activity. Both spectra show the differential response to left- versus right-circularly polarized radiation due to a vibrational transition in a chiral molecule. Vibrational circular dichroism (VCD) arises from simultaneous changes in the electric and magnetic dipole moments of the molecule due to the nuclear motion. The vibrational transition is between the g_0 and g_1 vibrational sublevels of the ground electronic state. The transition dipole coupling is highly dependent on peptide secondary structure. Because the interpretation of VCD depends on band shape, it is less susceptible to error from frequency shifts arising from nonstereochemical sources.

The amide I band (amide I′ in D_2O), due to primary C−O stretch, is the most

characteristic and the easiest to identify with VCD. Its frequency is relatively free of overlapping transitions from other parts of the molecule. An α-helix has a major positive peak at $\sim$1640 cm^{-1}. An antiparallel β-sheet has a split amide I′ band, with a major, sharp positive peak at $\sim$1615 to 1620 cm^{-1} and a weaker positive one at $\sim$1690 cm^{-1}. Random coil conformations give a broad positive peak at $\sim$1650 cm^{-1} and a positive trough at $\sim$1620 cm^{-1}, which is quite universal in band shape and intensity in most oligo- and polypeptides.

The amide II band is a mixture of N−H deformation and C−N stretch. The differences among α-helix, β-sheet, and random coil are less clear than those with the amide I band. The distinct feature of the amide II VCD for the α-helix is a dominant negative band; for β-sheet one observes a negative couplet and for random coil there is a weaker intensity positive band. The amide III band of an α-helix is mostly positive in the region of $\sim$1350 to 1250 cm^{-1}, and for β-sheet it is mostly negative in the same region. The amide III band is more sequence dependent, which affects its ultimate utility for peptide backbone conformational analyses.

VCD provides complementary data to electronic CD. The spectra are richer in information, but the instrumentation is not as developed or as widely used as that for electronic CD. The rotational strengths of vibrational transitions are much less intense than those of electronic transitions, which makes it a challenge to achieve the necessary signal/noise ratio. The technique has clear promise, but for the remainder of our discussion, we shall focus on electronic CD.

4 Estimation of Secondary Structure Content

The three-dimensional conformation of a protein can be specified by the dihedral angles of the backbone. Hydrogen-bonding patterns and particular values of dihedral angles lead to regular, local elements of structure, known as *secondary structure*. Secondary structures can be grouped into α-helices, β-sheet, β-turn, and random coil. As most peptides and proteins are mixtures of these four basic secondary structures, the overall mean residue ellipticity at a specific wavelength, $[\theta(\lambda)]$, is the sum of contributions from each secondary structure. It can be calculated by the equation:

$$[\theta(\lambda)] = f_\alpha[\theta(\lambda)]_\alpha + f_\beta[\theta(\lambda)]_\beta + f_\gamma[\theta(\lambda)]_\gamma + f_R[\theta(\lambda)]_R + \text{noise} \quad (6)$$

which is based on the fraction of each secondary structure type: α-helix (f_α), β-sheet (f_β), β-turn (f_γ), and random coil (f_R). As a first approximation, the CD spectrum of a protein is the sum of the appropriate percentages of each component spectrum, but the relative arrangements of structural units and motifs may also contribute to the observed CD spectrum.

There are many computer programs that can analyze CD spectra to estimate protein secondary structure content. The major methods are either algorithm-based or rely on databases. The former includes constrained least squares, normalized least squares, singular value deconvolution, parameterized fit and neural networks. Frequently used software packages are SELCON3, CONTIN, and Varslc. Database approaches are available in SELCON3, CONTIN, and SELCON. Most of these facilities can be found on the web site: http://www.cryst.bbk.ac.uk/cdweb.

The variable selection-self-consistent program SELCON provides analysis based on a database of 17 proteins. In SELCON, the proteins in the database are arranged in an order of increasing root-mean-square difference from the spectrum; the spectra least like the spectrum of interest are deleted to increase the speed. Then the program utilizes the observation that prediction improves when the protein is included in the basis set. The initial guess of the structure of the protein is made, and the secondary structure of the protein is then determined. The solution replaces the initial guess and the process is repeated until self-consistency is attained. This program gives a fairly accurate estimation of α-helix, β-sheet, and β-turn of globular proteins based on CD spectra between 240 and 200 nm. However, it overestimates α-helix and underestimates β-sheet when polypeptides have high β-sheet content.

The neural network program, K2D, uses a learnt mapping between spectra and secondary structure content to analyze new experimental spectra. It was trained on input data, which were CD spectra represented as 41 inputs corresponding to the intensities at the wavelengths between 240 and 200 nm. The output units formed a self-organized map, which could be analyzed to give fractional weights of protein secondary structures. In the training phase, the weighting of each wavelength is altered, until the error between the calculated and actual secondary structure content for the training data is minimized. For a new spectrum, the data are fed through the network using the adjusted weights to give an estimate of the secondary structure content. The K2D program predicts the secondary structure content fairly well, but does not give a matched spectrum. A different type of neural network was used, in which the output units gave directly the fractional secondary structure content: α-helical, parallel and antiparallel β-sheet, β-turn, and others. The network was trained on 13 spectra, each represented as 83 inputs corresponding to the intensities from 178 to 260 nm.

Each of these methods and programs has its advantages and disadvantages. Even when a method provides a good match between the calculated spectrum and the experimental data, it may not necessarily provide the best estimation of protein secondary structure content. Among these methods, SELCON may perform better than the others. Most of these programs usually estimate α-helical content well, but underestimate β-sheet and β-turn contents.

5 Experimental Aspects

5.1 Instrumentation

Nowadays, measuring CD is routine work in many laboratories. There are four manufacturers of CD instruments. Aviv and Associates (Lakewood, New Jersey) has Cary 61 and 62 CD instruments with a photoelastic modulator, modernized electronics, and a computer control system. JASCO (Easton, Maryland and Tokyo) makes J710 and J720 spectrometers. Jobin-Yvon (Longjumeau, France) manufactures the JY Mark VI and OLIS (On-Line Instrument Systems, Bogart, Georgia) offers the Cary 61 and 62 CD instruments. CD accessories for stopped-flow instruments are available from Applied Photophysics Ltd. (Leatherhead, UK) and Biologic (Grenoble, France).

Most instruments use a single beam. In Eq. (2), the intensity of the incident

light, I_0, does not appear for calculation of absorbance, so there is no need for a reference beam in measurements. However, a new double-beam instrument made by OLIS using sample and reference beams permits direct calculation of the CD signal. This technique reduces drift over time and factors such as lamp fluctuations are negated, since they affect both beams equally.

The light source is usually a 150 or 450 W xenon arc, which provides a continuous spectrum from the edge of the vacuum UV into the infrared region. Linearly polarized light from a monochromator passes through a modulating device, a photoelastic modulator, which converts the plane-polarized light to circularly polarized light, alternating between left- and right-circularly polarized light at the modulation frequency. In the detection end of the spectrometer, the light intensity is also modulated at the same frequency as the incident light.

A different modulation method, digital subtraction, is used by OLIS. The unique aspect of this method is that both of the two diverging orthogonally polarized beams are rotated by 180°. Then, the digitized signals from the two photomultiplier tubes are combined in such a way as to yield the CD signal directly and to cancel the contributions of noise. So, in this system, the absolute CD is measured and no calibration is required. However, one shortcoming is that the two beams pass through different parts of the sample and the cuvette; the significance of this is still uncertain.

The cooling system of the instruments is usually water or a narrow bore central heating system pump with car radiator cooling fluid. If it is possible, an air-cooled lamp may give better performance. Nitrogen flow is needed to avoid the creation of ozone, which reacts with surfaces of the mirrors. Nitrogen may also keep oxygen from entering the sample compartment, as it absorbs the incident light.

High quality quartz cuvettes, which transmit the full wavelength range of UV–vis light, are required for CD experiments. Cuvettes have rectangular and cylindrical shapes. A cylindrical cuvette has lower birefringence than a rectangular shaped one. However, rectangular cells are more often used especially in titration experiments. Different pathlength cuvettes are used for measurements at different wavelengths. Ten and 1 mm pathlengths cannot be used for wavelengths under 200 and 190 nm respectively. For shorter wavelengths, and for more strongly absorbing solvents at longer wavelengths, cells of 0.1 or 0.05 mm are necessary. For these cells, as the total volume is small, a higher concentration is demanded to keep absorbance of more than 1.0.

5.2 Measurements

For measurements in the far UV, solvent absorbance is not negligible, even with aqueous solutions. It is necessary to check the CD signal as a function of concentration to have a maximum absorbance of less than 1.5. If a linear relationship of absorbance as a function of concentration is not there, then there are solute–solute interactions in the sample. A baseline spectrum should be collected of solvent and buffer under the same conditions as the sample spectrum.

The spectrometer scans from longer to shorter wavelengths. Initially, the examining wavelength should be set 20 nm longer than that demanded by the experiment and it should be established that in this region

the absorbance is zero. Otherwise, it may be necessary to clean the cuvette and test again. The signal-to-noise ratio depends on many factors: it increases as $n^{1/2}$ (where n is the number of measurements), $I^{1/2}$ (where I is the intensity of light beam), and $\tau^{1/2}$ (where τ is the measuring time for each point). The CD instrument must be calibrated regularly using a standard sample. The most commonly used standard for visible and UV measurements is (+)-10-camphorsulfonic acid (CSA).

5.3 Solvents and Temperature Effects

The amount of sample required for CD experiments is relatively small compared to other absorption spectroscopic techniques. Water is the most frequently used solvent for CD measurements because of its excellent UV transparency. Fluorinated alcohols, such as 2,2,2-trifluoroethanol (TFE) and 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP), are good solvents as well. However, secondary structure, especially of peptides, can be influenced by solvents, for example, trifluoroethanol promotes α-helical conformations and nonpolar solvents, such as lipids and destabilize α-helices. MeCN is a good organic solvent. Phosphate buffers are also useful due to their low absorbance. However, some common salts and buffer components do significantly interfere with the far UV spectra and are best avoided.

Temperature may have a significant effect on CD spectra. When the free energy, difference between two conformations of a molecule, ΔG, is not too much higher than RT in the range of accessible temperatures (where R is the universal gas constant), a mixture of both conformers can be expected in solution. In this case, modifications of the experimental conditions can lead to a change in the measured rotational strength and can be calculated by

$$R_{\text{obs}} = \frac{R_1 + R_2 \exp(-\Delta G/RT)}{1 + \exp(-\Delta G/RT)} \qquad (7)$$

where R_1 and R_2 are the rotational strengths of these two conformers. Even when there is no a temperature-sensitive conformational change, there are temperature effects on CD spectra. For short helices, the temperature coefficient is small, but it increases significantly with helical length.

5.4 Stopped-flow

Stopped-flow CD is used for kinetic measurements of conformational transitions in proteins and in protein folding studies. It has been applied in the near UV and the far UV. The principle of stopped-flow is straightforward. The apparatus uses a drive motor to mix together rapidly two solutions, contained in separate drive syringes, into a mixing cell. The solutions then flow into the observation cell displacing the previous contents with freshly mixed reactants. A stop syringe is used to limit the volume of solution expended with each experiment and abruptly stops the flow. The flow of solution into the stop syringe causes the plunger to move back and trigger data collection. Then CD spectra may be measured as a function of time.

The primary objective of the stopped-flow experiments is to investigate transient changes in chiroptical properties associated with chemical, biochemical, and biophysical reactions, such as structural changes undergone during protein folding on a millisecond (ms) time scale and refolding. In many cases, secondary

structure is formed rapidly within 2 to 5 ms, and tertiary structure is formed slowly. The two-state folding of a small protein may occur within 3 ms. Stopped-flow measurements require relatively few combined shots to provide folding kinetics data. It can be made over a wide wavelength range, allowing the collection of time-resolved CD spectra. These can be analyzed to provide time-courses of the development of individual secondary structure types. However, the limitation of stopped-flow is the ''dead-time'' of the mixing process, which is typically more than 2 ms. In order to study faster folding kinetics, temperature-jump methods can be employed to shorten the observing time to 10 ~ 20 ns with laser-induced rapid heating (discussed in Sect. 5.6). In general, stopped-flow only provides average information of the secondary structure of protein; it cannot specify precisely where the secondary structure is formed.

5.5 Synchrotron Radiation

The X-ray source for measuring an X-ray absorption spectrum is synchrotron radiation. It covers all the wavelengths of the electromagnetic spectrum with an intensity over 100 times higher than the conventional X-ray tubes. When charged particles (electrons or positrons) from a linear accelerator with a speed close to that of light are injected into a storage ring under high vacuum, the magnetic fields from the strong bending magnets around the ring force the accelerated electrons to follow the ring in the curved sections. The high-energy particles hit the curved parts and lose part of their energy as synchrotron radiation, which is emitted tangential to these curved sections.

Synchrotron radiation CD has been developed for more than 20 years, but it has been used only recently in protein secondary and tertiary structure analysis. Synchrotron radiation CD provides higher photon fluxes of linearly polarized light particularly at short wavelengths than conventional sources. There is no need of a polarizer and the measuring limit extends to the cut-off of the photoelastic modulators (usually 120–130 nm) with much higher signal-to-noise ratio. So, CD spectra can be collected to a lower wavelength limit, allowing more accurate secondary structure content on folding motifs and a high-intensity light source may work well in the presence of salts, buffers, and detergents as well. Collection times for synchrotron radiation CD spectra can be considerably shorter than with conventional instruments.

5.6 Fast Time-resolved Techniques

In order to study protein folding on short time scales, fast time-resolved CD has been developed. It is now possible to resolve motions of chromophores well into the subpicosecond time scale. Time-resolved spectroscopy determines the spectral properties of a material at various instants of time after a stimulus has been applied. There are two main approaches: signal gating by sampling the output of a fast-responding photodetector and probing with a short-duration pulse of light. The limitations of the former are that few detectors operate at long wavelengths and the signal-to-noise ratio would be unacceptable. The pump-probe technique overcomes these limitations. It provides high temporal resolution of repeatable, photostimulated events.

Time-resolved CD can provide information on structural rearrangement and folding for both smaller chiral species and large macromolecules in different environments. Conventional time-resolved CD spectroscopy is limited by the time scale of the polarization modulator employed. Now, with shorter-pulse He–Ne lasers and a photoelastic modulator to alternate the pump laser polarizations without limiting the time response of the measurement, it is possible to detect the inherently weak difference between two large absorption signals, which are ellipsometric and are subject to significant optical artifacts. The limitation is the pulse length of the grating forming (pump) laser. Measurements can be made on microsecond, nanosecond, and picoseconds timescales. Although picosecond resolution is achievable, there are some technical problems, including intensity instability, polarization scrambling, and tunability limitations.

6
Spectral Characteristics of Elements of Protein Structures

CD is commonly used to probe the secondary conformations of proteins to study protein folding and to investigate interactions of proteins with small molecules such as achiral molecules whose induced CD is due to their interaction with the protein. Changes in CD can be used to provide evidence for conformational changes and to determine equilibrium constants. A few examples of conformational transitions are the α-helix to β-sheet conformational switch in the prion protein as the concentration of sodium dodecyl sulfate is altered; the unfolding of the coiled-coil structure of fibrinogen binding protein as temperature increases; the increasing helical content of troponin-C on binding Ca^{2+} and the binding of molybdate by the protein ModE, which gives large changes in the Trp signal at 292 nm. Far UV and near UV CD can be used to monitor protein unfolding upon the alteration of pH or the addition of a denaturant, such as urea or guanidinium chloride (GdmCl). CD can also be used to examine the interactions between multiple domains of proteins, for example, the flavin domain and the heme domain of flavocytochrome P450-BM3 give characteristic changes in the environment of the cofactors when they are linked in the intact enzyme.

6.1
α-helix

The right-handed α-helix (Fig. 4) has main-chain hydrogen bonds between amino acid residues and positions i and $i+4$ along the backbone chain. There is a 0.15-nm translation and a 100° rotation between two consecutive peptide units. Its helical pitch (the number of residues multiplied by the distance between α-carbon atoms on neighboring residues) is 0.54 nm. The α-helix has three distinctive bands in the far

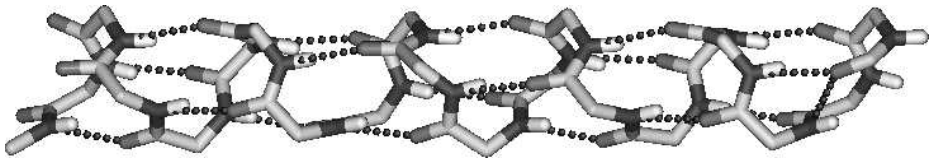

Fig. 4 The main chain of a polypeptide in an α-helical conformation, with hydrogen bonds denoted by dashed lines.

UV CD spectrum: two negative bands with separate minima of similar magnitude at 222 nm (the $n\pi^*$ transition) and 208 nm (the parallel $\pi\pi^*$ exciton band) and a positive band, the NV_1 band, at 190 nm due to the antiparallel $\pi\pi^*$ exciton band. The ratio $[\theta]_{208}/[\theta]_{222}$ is sensitive to the backbone dihedral angles.

The average fractional helicity, f_H, of an N-residue peptide may be related to the observed mean residue molar ellipticity at 222 nm by

$$f_H = \frac{[\theta]_{222}}{[\theta_{H\infty}]_{222}(1-k/N)} \qquad (8)$$

where $[\theta_{H\infty}]_{222}$ is the ellipticity of an infinite, completely helical peptide, k is an end-effect correction, which is $\sim$3, and N is the number of residues. Estimated values for $[\theta]_{222}$ of an infinite, completely helical peptide range from $-37\,000$ to $-44\,000$ deg cm^2 dmol^{-1}. However, anomalously intense bands have been observed in some peptide models under certain experimental conditions.

6.2
3_{10}-helix

The 3_{10}-helix has $(i, i+3)$ main-chain hydrogen bonds. There are three representative dihedral angles (φ, ψ) for 3_{10}-helices, type I $(-60^\circ, -30^\circ)$; type II $(-54^\circ, -28^\circ)$, and type III $(-44^\circ, -33^\circ)$. The three types of 3_{10}-helices are anticipated to have different CD spectra based on first-principles calculations. The CD spectrum for a type I 3_{10}-helix is similar to that for an α-helix, but a little weaker band at 222 nm relative to the 208 nm band, and the $[\theta]_{222}/[\theta]_{208}$ ratio ranges from about 0.3 to 0.85; this ratio is greater than 1 for an α-helix. Type II has the strongest experimental foundation; type I and III have weaker and stronger $n\pi^*$ transitions than type II, respectively. It may be possible to distinguish reliably between 3_{10}-helix and α-helix by CD, but it is still a matter of debate.

6.3
β-sheet

β-sheets are composed of β-strands, which can be thought of as helices with two residues per turn. Typical backbone dihedral angles are $\phi = -120^\circ$ and $\psi = +120^\circ$ producing a translation of 3.2 to 3.4 Å per residue for residues in antiparallel and parallel strands respectively. An antiparallel arrangement is shown in Fig. 5. The CD spectra for β-sheet proteins are less intense and have fewer features than those of α-helical proteins, with a negative band near 217 nm, a positive band near 195 nm, and another negative band near 180 nm. However, the CD spectra for β-sheet proteins have much greater variability than those for α-helices: for example, the intensities

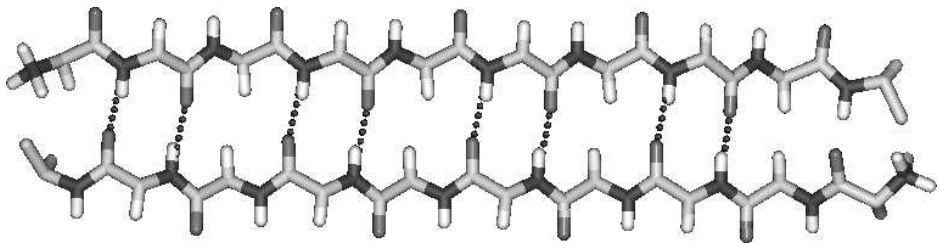

Fig. 5 The main chain of a polypeptide in an antiparallel two-stranded β-sheet, with hydrogen bonds depicted by dashed lines.

of the two long-wavelength bands, their ratio, and the wavelength of the positive band. These can be affected by side chains, solvents, and other environmental factors. Structural factors may also be important; β-sheets can be antiparallel, parallel, or mixed, intra- or intermolecular, and are also twisted to varying extents. Theoretical studies suggest that the extent of twisting of β-sheets is probably more important than the distinction between antiparallel and parallel sheets.

The wavelength at which the intensity of the CD spectrum changes sign is the most convenient criterion for differentiating parallel and antiparallel β-sheets. Crossover at ~178 nm indicates antiparallel β-sheet, at ~192 nm, parallel β-sheet, and at ~187 nm, a mixture of parallel and antiparallel β-sheets. The effects of twisting on β-sheet CD are predicted to include large differences in the magnitudes of the two long-wavelength bands, and a red-shift of both the positive maximum and the short-wavelength crossover from positive to negative CD.

Unlike α-helix content, it is not possible to estimate β-sheet content in proteins reliably from CD spectra because of the twisted and planar β-sheet showing quantitative differences between parallel and antiparallel β-sheet. One method is to calculate the difference between the CD at 217 nm and 195 nm. For 100% β-sheet, it is $50–55 \times 10^3$ deg cm^2 dmol^{-1}. This type of estimate may be reasonable, as long as the β-sheet is not strongly twisted.

6.4 *β*-turn

There are eight types of β-turn, three of which are common in proteins. The CD spectra of β-turn are rather varied. The type II β-turn has a strong negative band between 180 and 190 nm, a strong positive band between 200 and 205 nm, and a weak, red-shifted band at 225 nm due to the $n\pi^*$ transition. Generally, type II CD spectra are similar to β-sheet CD, except that the maximum is red-shifted by 5 to 10 nm. The CD spectra for type I and III turns are similar to that of the α-helix, with a negative $n\pi^*$ band and a negative $\pi\pi^*$ couplet.

6.5 Random Coil

CD spectroscopy is sensitive to precise protein conformation, but most random coils are very flexible. So, there are less common features in their CD spectra, except a strong negative band near 200 nm and a weak band at longer wavelengths, but the latter band may be either positive or negative. Poly(Glu) and poly(Lys) are frequently used models of unordered polypeptides. Their neutral aqueous solution spectra show two characteristic features: a strong negative band near 200 nm ($[\theta]_{max} \sim -40\,000$ deg cm^2 dmol^{-1}) and a significant band shift between 200 nm and 191 nm. When the pH is set to neutralize the side chains, or the ionic strength is increased by added salt, or the temperature is increased, the very weak negative band in the 235- to 240-nm region is observable. Urea and guanidinium chloride (GuCl) can have a complicated effect on CD spectra. At low concentrations, GuCl causes a decrease in the long-wavelength CD bands of the charged polypeptides by shielding the charges on the side chains and decreasing the electrostatic stabilization of the helical peptide.

There are two different explanations for unordered polypeptides CD spectra. In the conventional view, random coil polypeptides exist as an ensemble of an enormous

number of different conformers, with the relative geometry of nearest neighbors determined statistically. Another opinion is that fully ionized poly(Glu) and poly(Lys) at low temperature and low ionic strengths are in an extended helix conformation, which is similar to the left-handed 3_1 helix of poly(Pro)II helix. Theoretical calculations suggest that the parallel-polarized $\pi\pi^*$ transition occurs as a positive peak at 209 nm and that the perpendicular-polarized component is at 201 nm with a negative rotational strength. In general, random coil structures with different sequences and under different conditions can give a variety of CD curves. However, it seems likely that unordered polypeptides that have a positive band near 218 nm may have a substantial amount of poly(Pro)II helical conformation.

6.6 Polyproline Helices

The homopolymer poly(Pro) can adopt two different conformations. Poly(Pro) I is a right-handed helix with *cis*-peptide bonds throughout and it is stable only in relatively nonpolar solvents such as *n*-propanol. Poly(Pro)II is a left-handed 3_1-fold helix with trans residues. These two types of polyproline helices have different CD spectra. Poly(Pro)I has a strong positive band at ~215 nm and a slightly weaker negative at ~195 nm. Poly(Pro)II has a weak positive band at ~230 nm and a strong negative band at ~205 nm of ellipticity $\sim -60\,000$ deg cm^2 dmol^{-1}.

6.7 Extrinsic Chromophores

The CD spectra above 300 nm can be used to study transitions in chromophoric prosthetic groups, metal ions, inhibitors, or substrate analogues. Proteins lacking prosthetic groups do not exhibit absorption or CD bands above 300 nm, except possibly for the tail of a disulfide transition or a tryptophan band just above 300 nm. The CD spectra of disulfides have a characteristic tail stretching beyond 300 nm. There are three mechanisms contributing to the CD of chromophores bound to proteins. An extrinsic chromophore may be inherently chiral. There may be coupling between electronic transitions on the extrinsic chromophore and chromophores in the protein. It is also possible that transitions of differing symmetry on the extrinsic chromophore may mix because of the electrostatic field of the protein. The last two mechanisms depend on both the extrinsic chromophore geometry and also the structure of the protein.

6.8 Membrane Proteins

There are two kinds of membrane proteins: extrinsic (or peripheral) and intrinsic (or integral). Extrinsic membrane proteins may be removed from the membrane, or solubilized, by mild treatment, such as shaking with a dilute salt solution. Intrinsic membrane proteins cannot be removed from the membrane without treatment that destroys the membrane structure, such as dissolving it with detergent. Membrane proteins are difficult to study in NMR or X-ray crystallography, since the use of detergents may affect the conformation. So, CD spectroscopy is a useful method for investigating the structure of membrane proteins.

Membrane proteins tolerate mildly disruptive detergents without loss of activity. To analyze the CD spectra of membrane proteins requires the known structures

of membrane proteins (determined by X-ray diffraction), of which there are relatively few. Nevertheless, it is possible to estimate secondary structures content from CD spectra of membrane proteins using approaches such as convex constraint analysis. Five component spectra have been identified. They are two different types of α-helices (the α-helix in the soluble domain and the α_T-helix for transmembrane α-helix), β-sheet, β-turn, and unordered conformation. The characteristics of CD spectra of α-helix, β-sheet, β-turn, and random coil have been discussed above. The α_T-helix has a positive band in the range of 195 to 200 nm. The intensity of the 208-nm band is slightly more negative than that of the 222-nm band. α_T-helix has a larger rotational strength than an α-helix in aqueous conditions. Membrane proteins are immersed in a much lower dielectric medium than soluble proteins, which may explain some differences. Another important factor may be that the average chain length of an α_T-helix is 25 residues, which is about twice that of an α-helix in a soluble domain.

CD spectra can give much information about membrane proteins, such as secondary structure, fold motifs, conformational changes, environmental effects, folding, and insertion into membranes. However, there are potential artifacts of differential scattering, absorption flattening, and wavelength shifts, which may affect the CD spectra. CD spectra of membrane proteins often exhibit various degrees of distortions in shapes, intensities, and/or positions of the CD bands, and shifts in crossover points. There have been several experimental and theoretical approaches for differentiating the CD bands from the artifacts of the membrane protein CD spectra.

7 Conclusion and Outlook

CD spectroscopy is a useful technique for detecting protein secondary structure quickly and quantitatively. It is also useful in following protein folding/unfolding processes with stopped-flow or faster time-resolved techniques. The development of transient VCD may present a significant advance in quantifying the timescales of motions of biological systems. Currently, there is ongoing research to improve the accuracy of estimates of protein secondary structure content. Making such estimates more quantitative remains a challenge, as there are many factors that may affect the intensity and wavelength of CD spectra. Temperature and solvents are important external factors; dihedral angles and hydrogen-bonding patterns are key internal factors. All of these can change the relative orientation of $n\pi^*$ and $\pi\pi^*$ transitions, which in turn can lead to different CD spectra. In general, CD spectroscopy is a rapid technique, which is sensitive to protein secondary structure. More reliable analysis of CD spectra may emerge from ongoing experimental and theoretical studies.

Keywords

Antibody Repertoire
The array of different antibody molecules that may be synthesized by the immune system.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.

Combinatorial Antibody Library
A large ensemble of antibody molecules expressed in a given vector, generally derived by the independent cloning of single heavy- and light-chain genes in the vector.

Panning
An affinity-based selection procedure for the isolation of an antibody phage with specificity for a desired antigen or epitope.

Phage Display
The expression of proteins or peptides on the surface of a filamentous bacteriophage.

Evolutionary pressure has driven the need for immune systems of considerable complexity and finesse. Indeed, to function efficiently, host immunity must be equal to the diversity and ingenuity of organisms that threaten the well-being of the animal. Antibody-mediated immune defense plays a pivotal role in this process. This article discusses the development and application of combinatorial antibody libraries, an approach to the generation of human monoclonal antibodies that began in the early 1990s and has generated increasing interest, both academic and commercial, ever since.

1 Overview

Antibody molecules are characterized by their ability to engage in high-affinity interactions of narrowly defined specificity. These properties make antibodies appealing as potential therapeutic agents. There are in fact several examples in which serum antibody preparations, derived from individuals with high serum titers against particular antigens or pathogens, have proven useful in the clinic. For example, the incidence of hemolytic disease of the newborn has decreased dramatically in countries where anti-rhesus D prophylaxis is practiced. There are, however, a number of problems inherent to hyperimmune serum that prevent its wider application. First, it is practically available only in limited supply. Second, because it is a blood product, hyperimmune serum cannot be guaranteed completely safe for the recipient. Outbreaks of hepatitis in Ireland and Eastern Europe, traced back to contaminated batches of anti-rhesus D hyperimmune sera, have underlined this concern. Most importantly, however, serum preparations are an extremely inefficient way of delivering useful antibodies. Even in the most favorable circumstances, only a small proportion of the antibody in such sera will possess the desired specificity.

The arrival of hybridoma technology presented the opportunity to produce large-scale quantities of rodent monoclonal antibodies of a desired specificity, but these antibodies elicit a strong immune response in humans and have proven to be of limited use for therapy. Moreover, the generation of human monoclonal

antibodies using hybridoma technology and Epstein–Barr virus transformation of human B-cells has met with only limited success, particularly when one considers the size of the available antibody repertoire in man. Consequently, much effort has been directed toward ''humanizing'' existing mouse monoclonal antibodies through grafting murine antigen-binding sequences (complementarity-determining regions) into a human antibody framework. This methodology is useful insofar as the immunogenicity of the final construct is considerably lower than that of the original murine molecule. Significantly though, extra manipulation of framework residues is often required to attain the affinity of the original mouse antibody, and the process is labor-intensive and time consuming.

Nevertheless, humanized monoclonal antibodies are being increasingly used in the clinic including in the treatment of breast cancer, lymphomas, Crohn's disease, rheumatoid arthritis, and graft rejection and in the prevention of respiratory syncytial virus (RSV) infection in premature infants. Combinatorial antibody libraries provide a rich source of diverse and fully human antibodies without the need for manipulation and so are expected to be used increasingly for generating antibodies for the clinic. Indeed, the first human antibody developed from phage libraries has recently been approved for human use.

2 Combinatorial Antibody Libraries

2.1 The Early Libraries: The Lambda Phage System

In the search for an alternative approach for generating human monoclonal antibodies, two developments were critical. The first was the demonstration that the antibody antigen-binding fragments Fab and Fv could be cloned and expressed in bacteria. To ensure correct folding and assembly of the antibody fragments (essential for retention of the binding characteristics of the parent molecule), the translated proteins were shepherded to the bacterial periplasm under the guidance of appropriate bacterial leader sequences. Second, and equally important to the emergence of combinatorial antibody libraries, was the use of the polymerase chain reaction (PCR) and a family of oligonucleotide primers to amplify antibody genes from a mixed population of antibody-producing cells. Taken together, these techniques meant that one could, by using an appropriate vector, express in bacteria the antigen-binding domains of an array of antibodies of any class and from any animal for which one had the antibody sequence for the construction of appropriate PCR primers: in effect, antibody repertoire cloning.
